13 (Dated: November 19, 2020)

14 Seasonal influenza viruses repeatedly infect humans in part because they rapidly change
15 their antigenic properties and evade host immune responses, necessitating frequent
16 updates of the vaccine composition. Accurate predictions of strains circulating in the
17 future could therefore improve the vaccine match. Here, we studied the predictability of
18 frequency dynamics and fixation of amino acid substitutions. Current frequency was the
19 strongest predictor of eventual fixation, as expected in neutral evolution. Other properties,
20 such as occurrence in previously characterized epitopes or high *Local Branching Index*
21 (LBI) had little predictive power. Parallel evolution was found to be moderately predictive
22 of fixation. While the LBI had little power to predict frequency dynamics, it was still
23 successful at picking strains representative of future populations. The latter is due to a
24 tendency of the LBI to be high for consensus-like sequences that are closer to the future
25 than the average sequence. Simulations of models of adapting populations, in contrast,
26 show clear signals of predictability. This indicates that the evolution of influenza HA and
27 NA, while driven by strong selection pressure to change, is poorly described by common
28 models of directional selection such as travelling fitness waves.

29 INTRODUCTION

30 Seasonal influenza A viruses (IAV) infect about 10% of 53
31 the global population every year, resulting in hundreds 54
32 of thousands of deaths (Organization, 2018; Petrova and 55
33 Russell, 2017). Vaccination is the primary measure to 56
34 reduce influenza morbidity. However, the surface proteins 57
35 hemagglutinin (HA) and neuraminidase (NA) continu- 58
36 ously accumulate mutations at a high rate, leading to fre- 59
37 quent antigenic changes (Petrova and Russell, 2017; Shih 60
38 et al., 2007; Bhatt et al., 2011; Koel et al., 2013). While 61
39 a vaccine targeting a particular strain may be efficient for 62
40 some time, antigenic drift will sooner or later render it ob- 63
41 solete. The World Health Organization (WHO) regularly 64
42 updates influenza vaccine recommendations to best match 65
43 the circulating strains. Since developing, manufacturing, 66
44 and distributing the vaccine takes many months, forecast- 67
45 ing the evolution of influenza is of essential interest to 68
46 public health (Morris et al., 2018; Klingen et al., 2018a). 69

47 The number of available high quality HA and 70
48 NA sequences has increased rapidly over the last 20 71
49 years (Bogner et al., 2006; Shu and McCauley, 2017) 72
50 and virus evolution and dynamics can be now be tracked 73

51 at high temporal and spatial resolution (Rambaut et al.,
52 2008). This wealth of data has given rise to an active
53 field of predicting influenza virus evolution (Morris et al.,
54 2018; Klingen et al., 2018a). These models predict the
55 future population of influenza viruses by estimating strain
56 fitness or proxies of fitness. Luksza and Lässig (2014),
57 for example, train a fitness model to capture antigenic
58 drift and protein stability on patterns of epitope and non-
59 epitope mutations. Other approaches by Steinbrück et al.
60 (2014); Neher et al. (2016) predict fitness by using hemag-
61 glutination inhibition (HI) data to determine possible
62 antigenic drift of clades in the genealogy of the HA pro-
63 tein. Finally, Neher et al. (2014) use branching patterns
64 of HA phylogenies as a proxy for fitness. These branching
65 patterns are summarized by the Local Branching Index
66 (LBI), which was shown to be a proxy of relative fitness
67 in mathematical models of rapidly adapting populations
68 (Neher et al., 2014).

69 The underlying assumption of all these methods is that
70 (i) differences in growth rate between strains can be es-
71 timated from sequence or antigenic data and (ii) that
72 these growth rate differences persist for long enough to be
73 predictive of future success. Specific positions in surface
74 proteins are of particular interest in this context. The
75 surface proteins are under a strong positive selection and
76 change their amino acid sequence much more rapidly than
77 other IAV proteins or than expected under neutral evo-
78 lution (Bhatt et al., 2011; Strelkowa and Lässig, 2012).

Epitope positions, i.e., positions targeted by human antibodies, are expected to change particularly often since viruses with altered epitopes can evade existing immune responses (Shih et al., 2007; Koel et al., 2013; Wolf et al., 2006). It therefore seems plausible that mutations at these positions have a tendency to increase fitness and a higher probability of fixation (Strelkowa and Lässig, 2012). But one has to be careful to account for the fact that these positions are often ascertained post-hoc (Shih et al., 2007) and human immune responses are diverse with substantial inter-individual variation (Lee et al., 2019).

In this work, we use HA and NA sequences of A/H3N2 and A/H1N1pdm influenza from year 2000 to 2019 to perform a retrospective analysis of frequency trajectories of amino acid mutations. We quantify how rapidly mutations at different frequencies are lost or fixed and how rapidly they spread through the population. We further investigate whether any properties or statistics are predictive of whether a particular mutation fixes or not. To our surprise, we find that the predictability of these trajectories is very limited: The probability that a mutation fixes differs little from its current frequency, as would be expected if fixation happened purely by chance. This observation holds for many different categories of mutations, including mutations at epitope positions. This weak predictability is not attributable solely to clonal interference and genetic linkage, as simulation of models including even strong interference retain clear signatures of predictability. Consistent with these observations, we show that a simple predictor uninformed by fitness, the consensus sequence, performs as well as the Local Branching Index (LBI), the growth measure based on the genealogy used in (Neher et al., 2014). This suggests that although LBI has predictive power, the reason for its success may not be related to it approximating fitness of strains.

qualitative question, is to ask whether X will fix in the population, will disappear, or whether the site will stay polymorphic.

We use amino-acid sequences of the HA and NA genes of A/H3N2 (since the year 2000) and A/H1N1pdm (since the year 2009) influenza available in GISAID (Shu and McCauley, 2017) (see supplementary materials for an acknowledgment of all data contributors). This amounts to 44 976 HA and 36 300 NA sequences for A/H3N2 and 45 350 HA and 40 412 NA sequences for A/H1N1, with a minimum of 100 per year. These sequences are binned in non-overlapping intervals of one month. Each single-month time bin and the sequences that it contains represent a (noisy) snapshot of the influenza population at a given date. The number of sequences per time bin varies strongly both with year and according to the season, with earlier time bins containing around 10 sequences while more recent bins contain several hundreds (see figures S7 and S8 in SM for details).

The central quantities that we derived from this data are *frequency trajectories* of amino acids at each position in the sequences. If an amino acid X_i is found at position i at a frequency between 5% and 95% in the population of a given time bin t , then the population is considered polymorphic at position i and at time t . This polymorphism is characterized by the frequency of X_i , $f_{X_i}(t)$, and also by frequencies of other amino acids at i . The series of values $f_{X_i}(t)$ for contiguous time bins constitutes the frequency trajectory of X_i . A trajectory is terminated if the corresponding frequency is measured above 95% (resp. below 5%) for two time bins in a row, in which case amino acid X_i is considered as *fixed* (resp. *absent*) in the population. Otherwise, the trajectory is considered *active*. Examples of trajectories can be seen in figure S9 of the Supplement.

In the rest of this work, we will focus on frequency trajectories that are starting at a zero (low) frequency, i.e. $f(t=0) = 0$. These represent new amino acid variants which were absent in the population at the time bin when the trajectory started and are currently rising in the population (see Methods). Such distinction in novel and ancestral variants is necessary to meaningfully interrogate predictability. Each rising trajectory of a new mutation implies the existence of another decreasing one at the same position, since frequencies of all amino acids at a given position must sum to one. If novel variants arise by selection, we expect to see a stronger signal of selection after conditioning on these novel variants. In classic models of population genetics, strongly advantageous variants undergo rapid selective *sweeps*, i.e., the rapid rise and fixation. The sweep of a mutation can be due to its own fitness effect, to the genetic background or to the effect of the seven other segments. By considering the ensemble of novel variants that are rising in frequency, we effectively average over backgrounds, obtaining a set of mutations that we expect to be beneficial on average. If such sweeps

RESULTS

The main underlying question asked in this work is the following: given a mutation X in the genome of influenza that we observe at a frequency f in the population at a given date, what can we say about the future of X ? The trajectory of a mutation will depend on its own effect on fitness, the contribution of the genetic background on the same segment, and the effect of the remaining seven segments. Here, we investigate properties of broad categories of mutations effectively averaging over different genetic backgrounds to isolate the effects intrinsic to the mutation.

First, we ask whether we can quantitatively predict the frequency of X at future times $f(t)$. In other words, having observed a mutation at frequencies (f_1, f_2, \dots, f_n) at dates (t_1, t_2, \dots, t_n) , what can we say about its frequency at future dates $(t_{n+1}, t_{n+2}, \dots)$? A simpler, more

are common in the evolution of HA and NA, the restriction to trajectories that start at low frequency should thus enrich for mutations that are positively selected and on their way to fixation.

Predicting future frequencies

Having observed the frequency trajectory $f(t)$ of a mutation until a given date t_0 , how much can we say about the future values of f after t_0 ? We consider the idealized case sketched in panel **A** of figure 1: given the trajectory of a *new* mutation, *i.e.* that started at a frequency of 0, and that we observe at frequency f_0 at time t_0 , what is the probability $P_{\Delta t}(f)$ of observing it at a value f at time $t_0 + \Delta t$?

To answer this question retrospectively, we use all frequency trajectories extracted from HA and NA sequences that satisfy these conditions for a given f_0 . The number of trajectories is limited and the frequency estimates themselves are based on a finite sample and are hence imprecise. Therefore, we consider trajectories in an interval $[f_0 - \delta f, f_0 + \delta f]$ with $\delta f = 0.05$.

For $f_0 = 0.3$, we found 120 such trajectories in the case of A/H3N2 influenza, represented on the panel **B** of figure 1, where time is shifted such that $t_0 = 0$. The same analysis was performed for A/H1N1pdm, with the 89 found trajectories displayed in figure S11. Some trajectories fall in the frequency bin around f_0 while decreasing, even though they crossed that bin at an earlier time. This is due to the fact that some trajectories “skipped” the interval f_0 in question on their initial rise due to sparse sampling. These trajectories are nevertheless rising in the sense that they start at frequency 0 for $t \rightarrow -\infty$. Removing them does not change results significantly.

Since rapid sequence evolution of influenza HA and NA mediates immune evasion, one could expect that a significant fraction of new amino acid mutations on rising trajectories in figure 1 are *adaptive*. We could thus expect that most of these trajectories continue to rise after reaching frequency f_0 , at least for some time. A fraction of those would then sweep through the population and fix.

To quantify the extent to which this preconception of sweeping adaptive mutations is true, we estimated the probability distribution $P_{\Delta t}(f|f_0)$ of finding a trajectory at frequency f after a time Δt given that it was observed at f_0 at time 0. The results for different Δt are shown in figure 1C. Initially, *i.e.* at time $t_0 = 0$, this distribution is by construction peaked around f_0 . If a large fraction of the trajectories keep increasing after this time, we should see the “mass” of $P_{\Delta t}(f|f_0)$ move to the right towards higher frequencies as time progresses.

However, future distributions for $\Delta t > 0$ do not seem to follow a pattern compatible with selective sweeps. The thick black line in Figure 1B shows the average frequency

of all trajectories. This average makes a sharp turn at $t = 0$ and is essentially flat for $t > 0$ in the case of A/H3N2, and slightly increasing for A/H1N1pdm (see supplement). Hence, the fact that this average rose for $t < 0$ gives little information for $t > 0$, and is due to the conditions by which these trajectories were selected. This shows that sweep-like trajectories rising steadily from frequency 0 to 1 are not common enough to dominate the average trajectory.

Consistent with the average, the frequency distribution of the selected trajectories broadens in time without a significant shift of the mean as time passes. After 60 days, the distribution is rather symmetrical around the initial $f_0 = 0.3$ value, suggesting that the knowledge that the trajectories were rising is lost after two months. On a timescale of 60 to 120 days, the only possible prediction is that trajectories are likely to be found in a broad interval around the initial frequency f_0 . After one year the distribution becomes almost flat (excluding mutations that have disappeared or fixed), and the initial peak at f_0 is not visible anymore. The only information remaining from the initial frequency is the fraction that fixed or was lost (see below). This behavior is expected in neutral models of evolution (Kimura, 1964) but incompatible with a dynamic dominated by sweeps taking over the population.

While this observation does not rule out that signatures exist that predict future frequency dynamics, past dynamics alone is weakly informative.

Prediction of fixation or loss

Instead of predicting future frequency, let’s consider the long-term goal of predicting the probability that a mutation fixes in the population. We first estimate the fraction of frequency trajectories that either fix in the population or are lost, as well as the time it takes for one or the other to happen. Panels **A** and **B** of figure 2 shows the fraction of frequency trajectories in HA and NA that either have fixed, were lost or remained active as a function of the time elapsed since they were first seen above 25% frequency. Most mutations are either lost or become fixed after 2-3 years, with very few trajectories remaining active after 5 years. This time scale of 2-3 years is consistent with the typical coalescence time observed in phylogenetic trees of A/H3N2 influenza (Rambaut et al., 2008; Yan et al., 2019). We also note that the fraction of lost trajectories increases sharply at small times with 40% of mutations observed above 25% frequency being lost within one year for A/H3N2, while it takes longer to fix a mutation in the whole population.

We then examined the probability of mutations to fix in the population as a function of the frequency at which they are seen. For different values of frequency f , we consider all trajectories that started at a null frequency

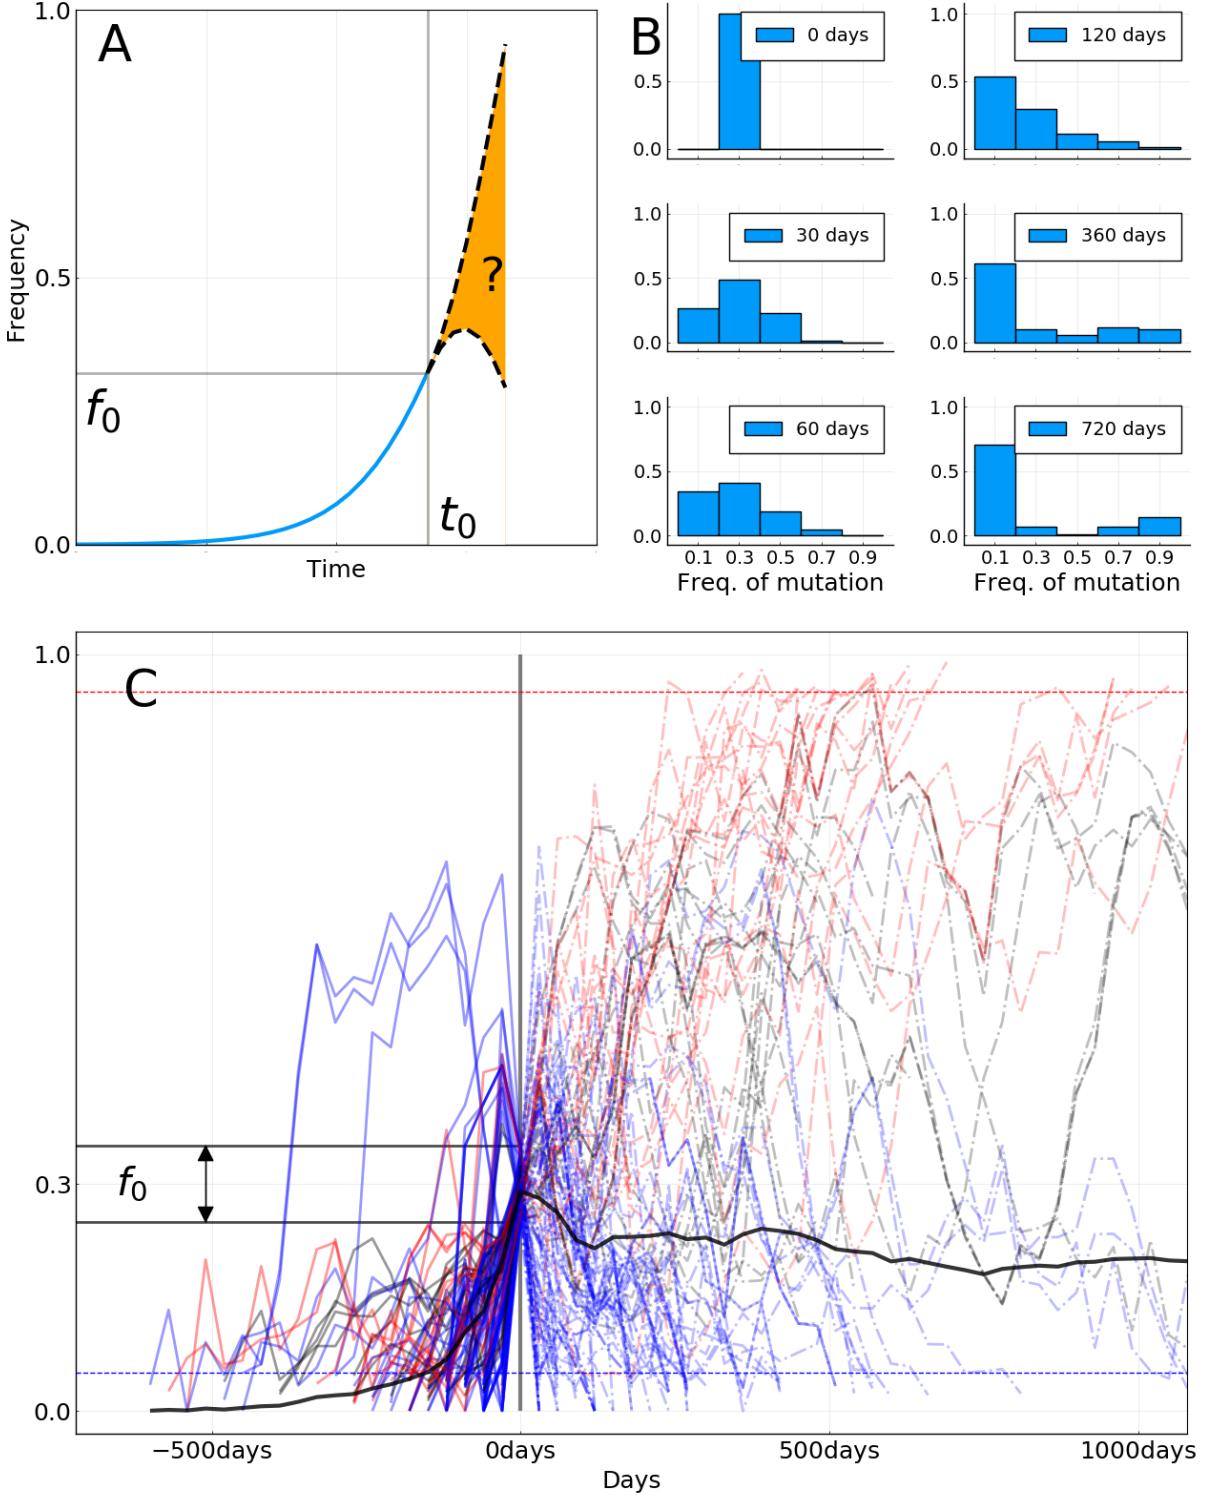

FIG. 1 **A:** Sketch of the idea behind the short term prediction of frequency trajectories. Given a mutation that we have seen increasing in frequency and that we “catch” at frequency f_0 at time t_0 , what can we say about the distribution of future frequencies $P_{\Delta t}(f|f_0)$? **B:** All frequency trajectories of amino acid mutations in the A/H3N2 HA and NA genes that were absent in the past, are seen around $f_0 = 30\%$ frequency at time $t_0 = 0$, and are based on more than 10 sequences at each time point. Red curves represent mutations that will ultimately fix, blue the ones that will be lost, and black the ones for which we do not know the final status. Dashed horizontal lines (blue and red) represent loss and fixation thresholds. The thick black line is the average of all trajectories, counting those that fix (resp. disappear) as being at frequency 1 (resp. 0). Figure S10 shows equivalent figures for other values of f_0 . **C:** Distribution of future frequencies $P_{\Delta t}(f|f_0)$ for the trajectories shown in panel **B** and for specific values of Δt .

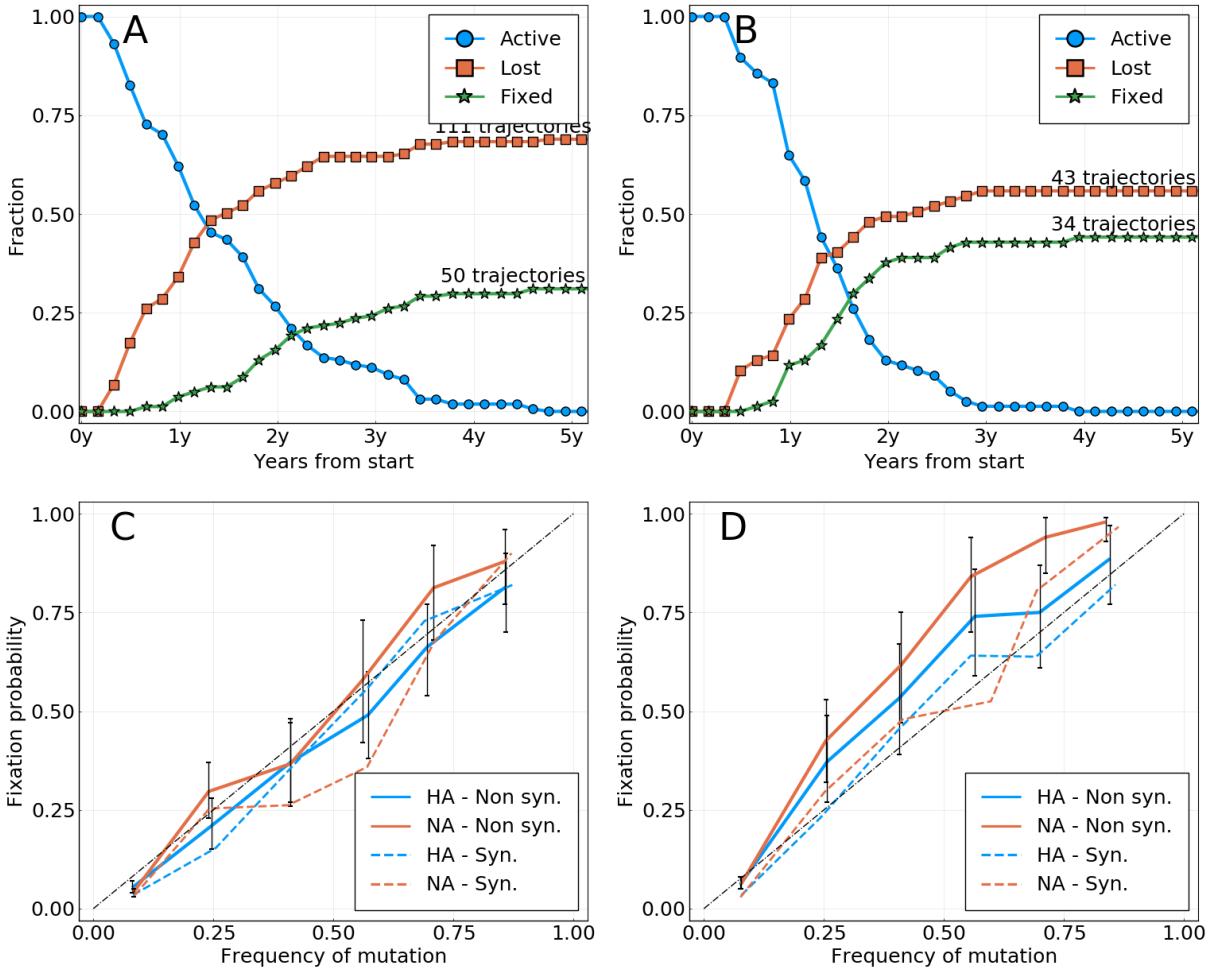

FIG. 2 **A:** Activity of all rising frequency trajectories seen above 25% frequency for A/H3N2 HA and NA. **B:** Same as **A** for A/H1N1. **C:** Probability of fixation of a mutation (amino acid or synonymous) $P_{fix}(f)$ as a function of the frequency f at which it is measured, for A/H3N2 HA and NA. Only new mutations are considered, *i.e.* mutations that were absent in the past. The diagonal dashed line is the expectation from a neutrally evolving population. Colored dashed lines represent synonymous mutations. Colored solid lines represent amino acid mutations. Error bars represent a 95% confidence interval. **D:** Same as **C** for A/H1N1.

and are seen in the interval $[f - 7.5\%, f + 7.5\%]$ at any given time. The probability of a mutation fixing given that it is seen at frequency f , $P_{fix}(f)$, is then estimated by the fraction of those trajectories which terminate at a frequency larger than 95%, *i.e.* our fixation threshold. Panels **C** and **D** of figure 2 show $P_{fix}(f)$ as a function of f for NA and HA. For both proteins, the probability of fixation of a new mutation at frequency f is close to f itself, that is $P_{fix}(f) \simeq f$. This result is exactly what is expected in a population evolving in the *absence* of selection. A mutation or trait appearing at frequency f is shared by $f \cdot N$ individuals, and the probability for one of them to become the ancestor of all the future population is $f \cdot N/N = f$. Thus, the probability of this mutation or trait to fix in the population is equal to its current frequency, a case which we will refer to as the neutral expectation. Panel **C** of figure 2 indicates that

mutations in the surface proteins of A/H3N2 influenza are in good agreement with the neutral expectation, while those in A/H1N1pdm show only small deviations from it. In both cases, the probability of fixation seems to be mainly dictated by the current frequency f at which the mutation is observed.

This dynamics is in apparent contradiction with evidence that influenza surface proteins are under strong selective pressure to evade human immune responses (Bhatt et al., 2011). If strong selection was present, we would expect rising amino acid mutations to fix at a distinctively higher frequency than the one at which they are measured. In an extreme case where most trajectories would be clean sweeps, $P_{fix}(f)$ should be close to 1 for all but very small values of f .

Next, we searched for features of mutations that allow prediction of fixation beyond frequency by dividing

328 frequencies into categories that deviate from the diagonal in panels **C** and **D** of figure 2. We first turn to the Local Branching Index (LBI), a quantity calculated for each node in a phylogenetic tree that indicates how dense the branching of the tree is around that node. LBI has previously been successfully used as a predictor of future population of influenza (Neher et al., 2014), and was shown to be a proxy for fitness of leaves or ancestral nodes in mathematical models of evolution. Here, we define the LBI of a mutation at date t as the average LBI of strains that carry this mutation and that were sampled in the time bin corresponding to t . Panel A of figure 3 shows fixation probability for HA mutations with LBI in the top or bottom half of the distribution. Both groups have identical probability of fixation, suggesting that LBI carries very little information on the probability of fixation of a mutation.

345 Next, we focused on previously reported antigenic sites in the A/H3N2 HA protein, referred to as *epitope* positions. Mutations at these position might mediate immune escape and are therefore likely under strong selection and show sweep-like behavior. We used four lists of relevant epitope positions from different sources comprising from 7 to 129 positions in the sequence of the HA1 protein (Shih et al., 2007; Koel et al., 2013; Luksza and Lässig, 2014; Wolf et al., 2006). Panel Fig. 3B shows fixation probability as a function of frequency for the four lists of epitopes. Only mutations at the 7 epitope sites reported in (Koel et al., 2013) have higher chances of fixation than expected by chance. No clear difference is found for the lists by Luksza and Lässig (2014); Wolf et al. (2006), while positions from Shih et al. (2007) show lower chances of fixation. One should also note that many of these positions were determined post-hoc and might be enriched for positions that experienced rapid substitutions before the publication of the respective studies.

364 Two ways of categorising mutations, however, suggest some power to predict fixation. In panel Fig. 3C, we split trajectories into those occurring at binary positions where only two amino acid variants co-circulate and non-binary positions with more than two variants. Novel variants at non-binary positions, *i.e.* ones for which competition between three amino acids or more has occurred at least once, have a higher chance of fixation. In panel D, we separated mutations that appear more than once or only once in the reconstructed tree (see methods), and found that the former fix more often. Panels C and D show that it is possible to gain some information on the chance of fixation of a particular mutation, as was done in panel B. However, the predictive power remains small, with the “top” curves in panels C&D being very close to the diagonal.

380 We conduct the same analysis on A/H1N1pdm influenza, with results shown in figure S13. Results are qualitatively similar to those obtained for A/H3N2, with LBI giving little information and mutations at non-binary

positions having a higher chance of fixation. Panel D differs between figures 3 and S13, with convergent evolution giving less information on fixation in the latter case. However, this could be due to the shorter time period over which A/H1N1pdm evolved, resulting in a shorter tree and less possibilities of convergent evolution. Indeed, error bars for mutations appearing multiple times in D of figure S13 are relatively large, indicating a lower amount of trajectories.

Since influenza is seasonal in temperate regions, geographic spread and persistence might be predictive of the success of mutations. We quantify geographic spread of a mutation by the entropy of its frequency distribution across regions (see methods) and its persistence by the age of the trajectory by the time it reaches frequency f . Figures S14 and S15 show the fixation probabilities as a function of observed frequency for mutations classified according to these scores. The two scores also allow a quantitatively moderate distinction between mutations: for a given frequency f , mutations found in many regions or those that are older (in the sense that they have taken more time to reach frequency f) tend to fix more often than geographically localized mutations or more recent ones, but the effect is small. These two scores are in fact correlated, with older trajectories representing mutations that are more geographically spread, as can be seen in figure S16 of SM. However, it is important to note that sampling biases and heterogeneity across time and space (see supplementary figures S7 and S8) make answering such specific hypothesis challenging. Frequency of mutations might thus be amplified through different sampling biases, making the connection between geographic spread, seasonality and mutation frequency non-trivial to measure.

Simulations of models of adaptation

The results shown in figures 2 and 3 are difficult to reconcile with the idea that seasonal influenza virus evolution is driven by rapid directed positive selection. One possible explanation for the weakly predictable behaviour of mutations (beyond their current frequency) might be tight genetic linkage inside each segment and strong competition between different adaptive mutations (Strelkowa and Lässig, 2012; Neher and Shraiman, 2011). We design a simple model of population evolution based on the `ffpopsim` simulation software to test this hypothesis (Zanini and Neher, 2012). The model represents a population of binary genomes of length $L = 200$ evolving in a fitness landscape that changes through time.

First, we use an additive fitness function, with sequence $(x_1 \dots x_L)$ having a fitness $\sum_i h_i x_i$. This implies that for a given genome position i , the trait $x_i = 1$ is favored if $h_i > 0$ whereas $x_i = -1$ is favored if $h_i < 0$. All h_i 's

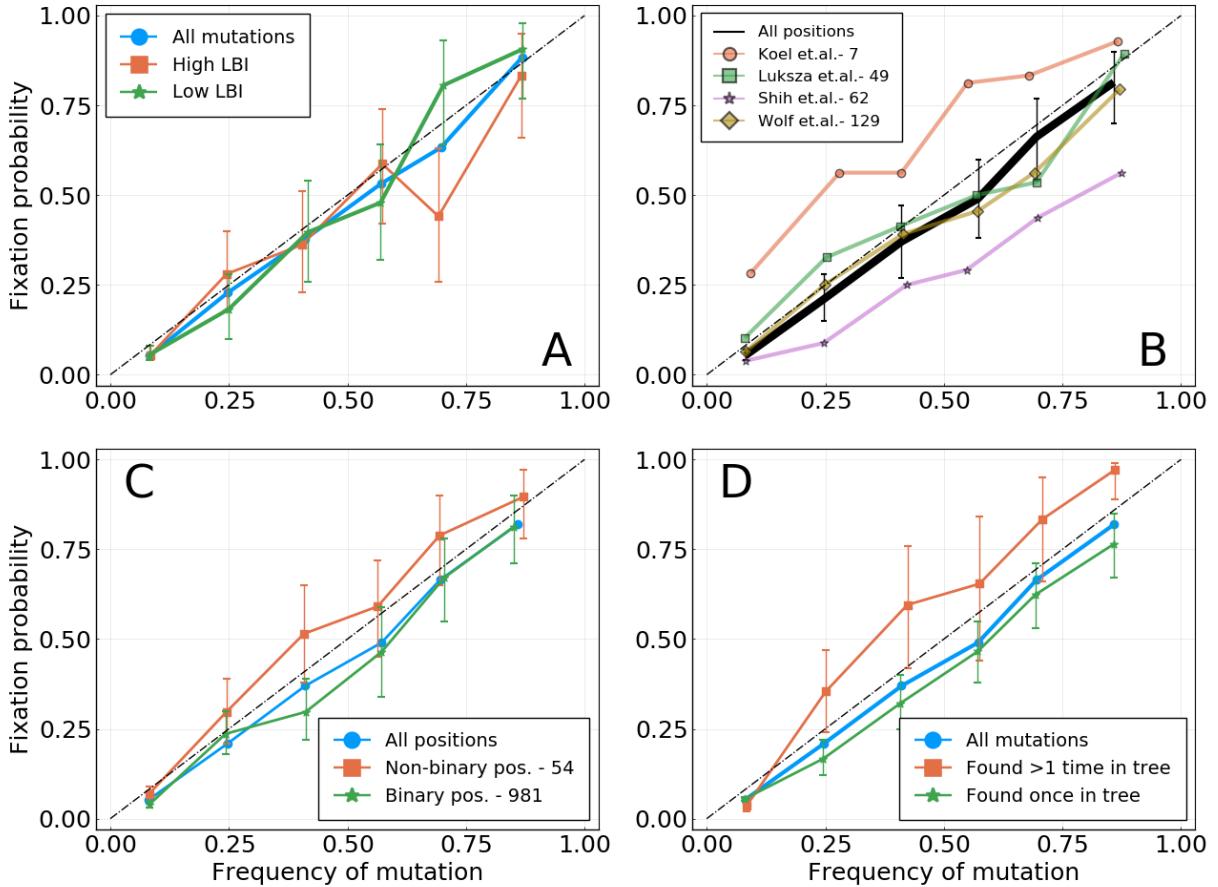

FIG. 3 Fixation probability $P_{fix}(f)$ as a function of frequency, for A/H3N2 influenza. Figure S13 shows the same analysis for A/H1N1. **A:** HA mutations with higher or lower LBI values, based on their position with respect to the median LBI value. **B:** Different lists of epitope positions in the HA protein. The authors and the number of positions is indicated in the legend. **C:** HA and NA mutations for binary positions, *i.e.* positions for which we never see more than two amino acids in the same time bin. **D:** HA and NA mutations that appear once or more than once in the tree for a given time bin.

437 have the same magnitude, and only their signs matter 457
 438 Every Δt generations, we randomly choose a position i 458
 439 and flip the sign of h_i , effectively changing the fitness 459
 440 landscape. Individuals in the population now have the 460
 441 opportunity to make an adaptive mutation at site i giving 461
 442 them a fitness advantage $2|h|$. A “flip” at position i of the 462
 443 fitness landscape will decrease fitness of all individuals 463
 444 that carried the adapted variant at position i and increases 464
 445 the fitness of those that happened to carry a deleterious 465
 446 variant.

447 To increase competition between genomes, we designed 467
 448 a second model that includes epistasis. Once again, the 468
 449 baseline fitness of a genome is an additive function, this 469
 450 time with values of h_i that do not change through time 470
 451 In addition, we added a component that mimics immune 471
 452 selection. Every Δt generation, we now introduce “an- 472
 453 tibodies” that target a specific sub-sequence of length 473
 454 $l = 5$, noted $(x_{i_1}^{ab}, \dots, x_{i_l}^{ab})$. The positions $(i_1 \dots i_l)$ are 474
 455 chosen at random, while the targeted sub-sequence is the 475
 456 dominant state at each position. Genomes that include 476

the *exact* sub-sequence targeted by the antibody suffer a strong fitness penalty. However, a single mutation away from that sub-sequence removes this penalty completely, resulting in a fitness landscape with very strong epistasis. This has the effect of triggering a strong competition between adaptive mutations: for a given antibody, $l = 5$ possible mutations are now adaptive, but combinations of these mutations do not bring any fitness advantage.

Having simulated populations in these two fitness landscapes, we perform the same analysis of frequency trajectories as for the real influenza data. Figure S18 of the SM shows the $P_{fix}(f)$ as a function of f for the two models and for different values of the inverse rate of change Δt of the fitness landscape. For all models, this curve deviates significantly from the diagonal. This is most evident for the case of a simple additive fitness landscape that changes rarely $\Delta t = 1000$: rising mutations almost always fix in the population, with $P_{fix}(f) \simeq 1$ for any f larger than a few percent. This is corroborated by visual inspection of the trajectories, which shows that evolution in this

regime is driven by regular selective sweeps that take a₅₃₀
typical time of ~ 400 generations. In other regimes, with₅₃₁
smaller Δt or with strong epistatic competition, $P_{fix}(f)$ ₅₃₂
is reduced and closer to the diagonal. However, it takes₅₃₃
an extremely fast changing fitness landscape to push P_{fix} ₅₃₄
close to the diagonal: with $\Delta t = 10$, that is about 40₅₃₅
changes to the fitness landscape in the time it would take₅₃₆
a selective sweep to go from 0% to fixation, $P_{fix}(f)$ differs₅₃₇
from f in a way that is comparable to what is observed₅₃₈
in A/H1N1pdm influenza.₅₃₉

These models are not meant to be accurate models of in₅₄₀
fluenza viruses evolution. But figure S18 does show is that₅₄₁
the patterns observed in influenza virus evolution are only₅₄₂
reproduced by models of adapting populations when push₅₄₃
ing clonal competition to extreme values. We conclude₅₄₄
that the pattern in figure 2 may not be a straightforward₅₄₅
manifestation of genetic linkage and clonal interference₅₄₆
but that some more intricate interplay of epidemiology₅₄₇
seasonality, human immunity and chance gives rise to₅₄₈
the weakly predictable yet strongly selected evolutionary₅₄₉
dynamics of IAVs.₅₅₀

498 Why do predictions work?

The statistics of frequency trajectories seem to be in₅₅₅
conflict with the notion that influenza evolution is pre₅₅₆
dictable. Likewise, the LBI, a quantity that correlates₅₅₇
with fitness in mathematical models and is used to predict₅₅₈
future influenza populations (Neher et al., 2014), does not₅₅₉
seem to contain any information on whether a specific₅₆₀
mutation is going to fix or not, see figure 3. To resolve₅₆₁
this conundrum, we first note that the criterion by which₅₆₂
predictive power for influenza was measured in (Neher₅₆₃
et al., 2014) was the distance between the strain with the₅₆₄
highest LBI and the future population, not the ability of₅₆₅
the LBI to predict dynamics. The distance was compared₅₆₆
to the average distance between the present and future₅₆₇
population, as well as the post-hoc optimal representative₅₆₈
and the future.₅₆₉

To quantify the ability of the LBI and other measures₅₇₀
to pick good representatives of the future, we construct₅₇₁
a large tree of HA sequences with 100 sequences in non₅₇₂
overlapping time bins of 4 months from year 2003 to 2019
(a total of 4402 as some 4 month intervals contain less
than 100 sequences). Each time bin is considered as a₅₇₃
snapshot of the A/H3N2 influenza population and we will
refer to sequences in time bin t as the population of the₅₇₄
present. From this present population, we predict future₅₇₅
populations in time bin $t + \Delta t$, using only sequences in₅₇₆
time bin t and before.₅₇₇

To assess the ability of the LBI to pick a close represen₅₇₈
tative of the future, we compute the LBI of each node of₅₇₉
one time bin in the tree using only the leaves that belong₅₈₀
to that time bin. The top panel in figure 4 shows the₅₈₁
hamming distance of the strain with the highest LBI to₅₈₂

future populations at different Δt along with the same
distance for a randomly chosen strain. The figure shows
the distance averaged over all possible values of t for Δt
between 0 and 32 months, giving us an average efficiency
of a predictor over 16 years of influenza evolution.

The strain with the highest LBI is consistently closer
to the future than the average strain by about 1-2 amino
acids, while the overall distance increases linearly due to
the continuous evolution of the population. We hence
reproduce previous results showing that the LBI picks
closer than average representatives (Neher et al., 2014).
To investigate whether this apparent success is due to the
ability of the LBI to predict fitness or not, we explored a
different predictor: the amino acid consensus sequence of
the present population (see Methods for a definition of
the consensus sequence). The choice is motivated by the
fact that it can be shown to be the best possible long term
predictor for a neutrally evolving population in terms of
Hamming distance (see SM section .1). Figure 4 shows
that the consensus sequence is in fact a equally good
or even slightly better representative of the future than
the sequence with highest LBI (note that the consensus
sequence does *not* necessarily exist in the population).

This near equivalence of the consensus and the strain
with highest LBI can be explained as follows: The LBI
tends to be high for nodes in a tree that are close to
the root of a dense and large clade. A typical sample
of influenza HA sequences fall into a small number of
recognizable clades, and the strains with maximal LBI
will often be close to the root of the largest of those clades.
This root of the largest clade will often be close to the
consensus of the whole population, explaining the similar
distance patterns. To test that hypothesis, we measure the
hamming distance from the sequence of the top LBI strain
to the consensus sequence for populations of all time bins.
Panel **B** of figure 4 shows these distances, scaled with
respect to an average strain (details in caption). It clearly
shows that the top-LBI strain and the consensus sequence
are indeed quite similar: out of 48 time bins, only once
is the sequence of the top-LBI strain farther away from
the consensus than the average sequence is. Moreover,
the sequence of the top-LBI strain *exactly* matches the
consensus in 19 cases.

DISCUSSION

Predicting the trajectory of a mutation requires (i)
significant fitness difference between genomes carrying
different variants at the site and (ii) a selection pressure
that changes slowly over time. Under such conditions, it is
expected that frequency trajectories will show a persistent
behavior which would make them predictable for some
time. However, we could find only limited evidence for
such persistent behavior in the past 19 years of IAV
evolution. This lead us to conclude that (i) influenza

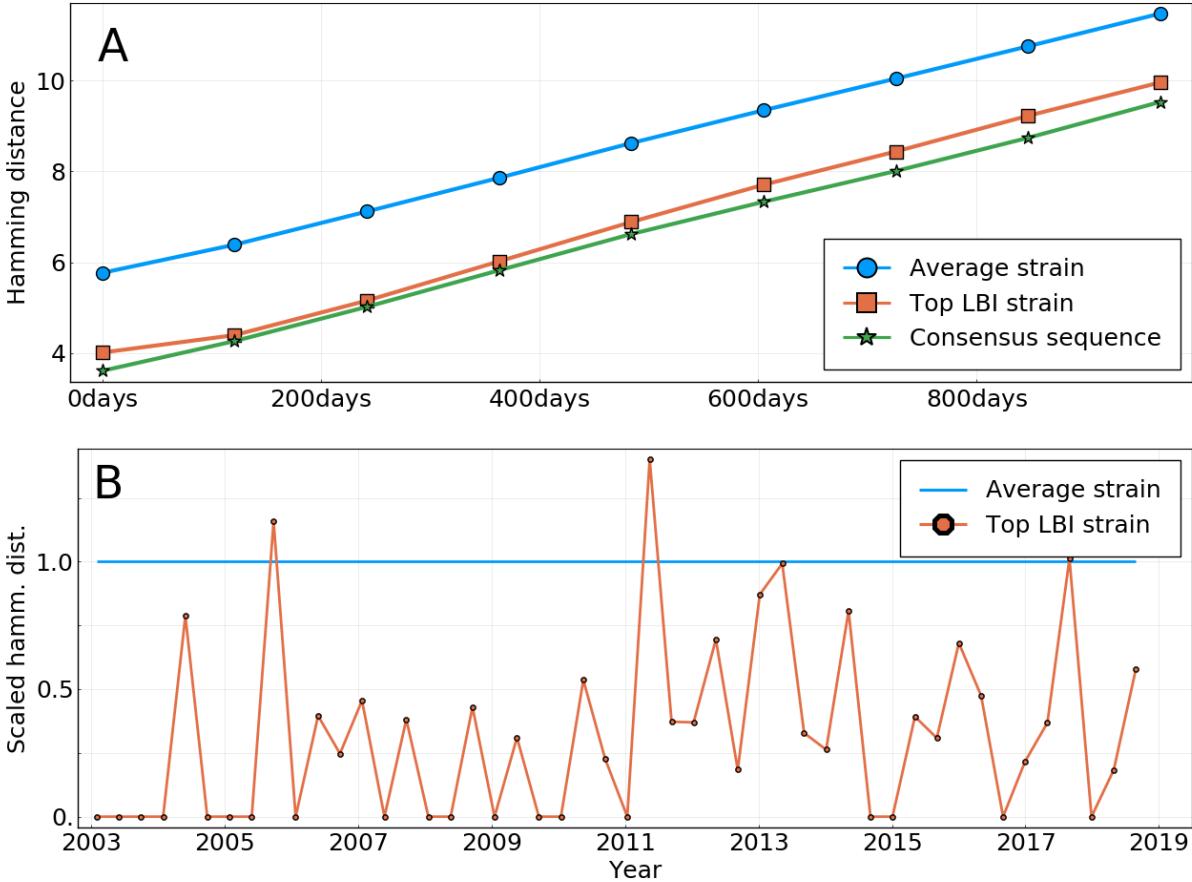

FIG. 4 **A:** Average Hamming distance of the sequences of different predictors to HA sequences of future influenza populations, themselves averaged over all “present” populations from year 2003 to 2019. Predictors are: a randomly picked sequence in the present population; the sequence of the strain with the highest LBI in the present population; the consensus sequence of the present population. **B:** Scaled Hamming distance between the sequence of the top LBI strain and the consensus sequence for populations at different dates. The scaling is such that for each date, the Hamming distance between a strain from the population and the consensus is on average 1. The strain with the highest LBI is almost always closer to the consensus sequence than the average strain.

virus evolution is qualitatively different from models of rapidly adapting population (despite clear evidence for frequent positive selection), and (ii) previous methods to predict influenza evolution work primarily because they pick strains that represent the future well, not because they predict future dynamics.

The primary focus in this work was the investigation of frequency trajectories of new amino acid mutations. In the short term, we found that on average the direction of trajectory does not persist for longer than a few months. Indeed, the average trajectory in figure 1 takes a sharp turn when going from $t < 0$ to $t > 0$, instead of showing “inertia”. This suggests that selective sweeps are not representative of typical trajectories. Pierre: We could cite the Illingworth paper here. They do show that as well, in a different way. The fact many trajectories are not sweeps is expected when there is strong linkage. What cannot be easily explained by linkage only is the complete

lack of inertia on average (at least I think?), and the $P_{fix}(f) = f$.

On a longer timescale, we investigated the probability that a novel mutation observed at frequency f fixes. In neutral models of evolution this probability equals f , while it should be higher or lower than f for mutations with a beneficial or deleterious effect on fitness, respectively. However, in the case of influenza, this probability differs little from f , making current frequency the best predictor for fixation. In figure 3, we split trajectories into groups for which we expected P_{fix} to deviate from f . Many of these splits, such as high/low LBI or epitope/non-epitope positions, did not result in an increased predictability, while others gave limited information on fixation. Despite the lack of predictability of mutation frequency trajectories, influenza surface proteins show strong signatures of selection (Bhatt et al., 2011; Strelkowa and Lässig, 2012).

Methods for predicting the future evolution of influenza

either construct explicit fitness models (Luksza and Lässig, 2014; Huddleston et al., 2020), use historical patterns of evolution (Luksza and Lässig, 2014; Bush et al., 1999), phenotypic assays (Neher et al., 2016; Steinbrück and McHardy, 2012), or dynamic or phylogenetic patterns (Neher et al., 2014; Klingen et al., 2018b). The goal of these methods is to pick strains that are good representatives of future populations and could serve as vaccine candidates (Morris et al., 2018).

The low power to predict frequency dynamics or fixation naturally triggers the question why the above methods have been found to work. Picking representatives of the future and predicting frequency dynamics are distinct objectives and success at the former (as compared to random picks) is not necessarily inconsistent with a lack of predictable dynamics. In fact, (Huddleston et al., 2020) reports that the rate at which the frequency of a strain changes is often a poor predictor – consistent with our observations here. But despite the fact that future frequencies are not predicted by the LBI, the strain with the highest LBI in the population is a better predictor of the future population than a randomly picked one. While the LBI was shown to be a correlate of relative fitness and be predictive of fixation in mathematical models of evolution (Neher et al., 2014), it does not seem to be predictive of influenza evolution because it measures fitness from genealogical structure. Instead, we believe it picks closer than average strains simply because it has the tendency to be maximal at the base of large and dense clades. These basal genotypes are closer to the future populations than the current tips of the tree and hence a better predictor on average. The consensus sequence of all present strains performs slightly but consistently better than picking the strain with the highest LBI. The consensus sequence is the best possible predictor for a neutrally evolving population, and does not attempt to model fitness in any way.

At the same time, influenza virus phylogenies show clear deviations from those expected from the neutral Kingman coalescent, similar to those expected under Bolthausen Sznitman coalescent (BSC) processes that are generated by traveling wave models of rapid evolution (Neher and Hallatschek, 2013; Desai et al., 2013). The correspondence between the BSC and traveling wave models comes from transient exponential amplification of fit strains before these fitness differences are wiped out by further mutation. This exponential amplification generates long tailed effective offspring distributions which in turn can lead to genealogies described by the BSC (Neher and Hallatschek, 2013; Schweinsberg, 2003). Many processes other than selection, including seasonality and spatio-temporal heterogeneity, can generate effective long tailed offspring distributions even in absence of bona-fide fitness differences, which might explain ladder-like non-Kingman phylogenetic trees.

A recent preprint proposed that influenza virus evo

lution is primarily limited by an asynchrony between population level selection and generation of new variants within infected hosts (Morris et al., 2020). Along these lines, it is possible that the A/H3N2 population readily responds once population level selection is high enough by giving rise to essentially equivalent variants. Furthermore, selection might cause the rapid rise of a novel variant to macroscopic frequencies (observable in a global sample) but its benefit rapidly “expires” because competing variants catch up and/or it mediates immune escape only to a small fraction of the population. These considerations might explain the disconnect between models of rapid adaptation and the frequency dynamics observed in influenza virus populations.

METHODS

Data and code availability

The sequences used are obtained from the GISAID database (Shu and McCauley, 2017). Strain names and accession numbers are given as tables in two supplementary files. Outliers strains listed at <https://github.com/PierreBarrat/FluPredictability/src/config> were removed.

The code used to generate the figures presented here is available at <https://github.com/PierreBarrat/FluPredictability>.

Frequency trajectories

For a set of sequences in a given time bin, we compute frequencies of amino acids at each position by simple counting. We make the choice of not applying any smoothing method in an attempt to be as close to the data and “model-less” as possible. This is especially important for the short term prediction of frequency trajectories, as estimations of the “persistence time” of a trajectory might be biased by a smoothing method.

We compute frequency trajectories based on the frequencies of amino acids. A trajectory begins at time t if an amino acid is seen under the lower frequency threshold of 5% (resp. above the higher threshold of 95%) for the two time bins preceding t , and above this lower threshold (resp. below the higher threshold) for time bin t . It ends in the reciprocal situation, that is when the frequency is measured below the lower threshold (resp. above the higher threshold) for two time bins in a row.

In order to avoid estimates of frequencies that are too noisy, we only keep trajectories that are based on a population of at least 10 sequences for each time bin. As said in the Results section, we also restrict the analysis to trajectories that begin at a 0 frequency, in part to avoid double counting. We find a total of 460 such trajectories. However, only 106 reach a frequency of 20%, on which

725 figure 2 is based for instance.

726 Note that the fact that we use samples of relatively small
 727 sizes – at least for some time bins – leads to biases in
 728 the estimation of frequencies. We show in Supplementary
 729 Material that these biases are generally small and do not
 730 induce any qualitative changes to results presented here.
 731

$G(X)$ is a positive quantity that is larger when X is
 762 equally present in many regions, and equal to zero when
 X is concentrated in only one region.

Region used are the ones defined in the **Nextstrain**
 tool (Hadfield et al., 2018). Those are North America,
 South America, Europe, China, Oceania, Southeast Asia,
 Japan & Korea, South Asia, West Asia, and Africa.

731 Local Branching Index

732 LBI was introduced in (Neher et al., 2014) as an approx-
 733 imation of fitness in populations evolving under persistent
 734 selective pressure that is fully based on a phylogenetic tree.
 735 It relies on the intuition that the tree below high-fitness
 736 individuals will show dense branching events, whereas
 737 absence of branching is a sign of low-fitness individuals.
 738 Quantitatively, the LBI $\lambda_i(\tau)$ of a node i is the integral
 739 of all of the tree’s branch length around i , with an expo-
 740 nentially decreasing weight $e^{-t/\tau}$ with t being the branch
 741 length. When considering a time binned population, the
 742 LBI is computed once for each time bin by considering
 743 only the leaves of the tree that belong to the time bin.
 744 This means that only branches that ultimately lead to
 745 a leaf that belongs to the time bin are considered in the
 746 integration.

747 τ is the time scale for which the tree is informative of
 748 the fitness of a particular node. Here, we use a value of
 749 τ equal to a tenth of $T_C \simeq 6$ years, the coalescence time
 750 for influenza A/H3N2 strains, converted to units of tree
 751 branch length through the average nucleotide substitution
 752 rate ($\simeq 4 \cdot 10^{-3}$ substitutions per site per year for HA).
 753 We have observed that given our method to predict the
 754 future from present populations corresponding to time
 755 bins of 4 months, changing the value of τ has little effect
 756 on the pick of the top LBI strain. By retrospectively
 757 optimizing its value, it is possible to reduce the average
 758 distance to the population 2 years ahead by ~ 0.25 amino
 759 acids on average, making the LBI method almost as good
 760 as the consensus on figure 4.

761 Measuring the geographical spread of a mutation

For a mutation X we define its regional distribution
 using the numbers $n_r(X)$ that represent the number of
 sequences sampled in region r that carry X . Regional
 weights are then defined as

$$w_r(X) = \frac{n_r(X)}{\sum_r n_r(X)}.$$

We can then measure the geographical spread $G(X)$ of X
 by using the Shannon entropy of the probability distribu-
 tion $w_r(X)$:

$$G(X) = \sum_r w_r(X) \log(w_r(X)).$$

769 Assigning a fitness to trajectories

Consensus sequence

Given a set of N sequences $(\sigma^1, \dots, \sigma^N)$ based on an
 alphabet \mathcal{A} (e.g. \mathcal{A} has 20 elements for amino acids, 4
 for nucleotides), we can define a *profile* distribution $p_i(a)$ by
 the following expression:

$$p_i(a) = \sum_{n=1}^N \delta_{\sigma_i^n, a}$$

where i is a position in the sequence, σ_i^n the character
 appearing at position i in sequence σ^n , a a character of
 the alphabet and δ the Kronecker delta. The profile $p_i(a)$
 simply represents the fraction of sequences which have
 character a at position i .

We then simply define the consensus sequence σ^{cons} such
 that

$$\sigma_i^{cons} = \operatorname{argmax}_a p_i(a).$$

In other words, the consensus sequence is the one that
 has the dominant character of the initial set of sequences
 at each position.

Earth Mover's Distance

In order to measure the distance of several predictor
 sequences to the future population, we rely on the *Earth
 Mover's Distance* (EMD), a metric commonly applied
 in machine learning to compare collections of pixels or
 words (Rubner et al., 1998; Kusner et al., 2015). Here, we
 apply it to compute the distance between the sequences
 of two populations, noted as $\mathcal{X} = \{(x^n, p^n)\}$ and
 $\mathcal{Y} = \{(y^m, q^m)\}$ with $n \in \{1 \dots N\}$ and $m \in \{1 \dots M\}$. In this
 notation, x^n and y^m are sequences, and p^n and q^m are the
 frequencies at which these sequences are found in their
 respective populations. For convenience, we also define
 $d_{mn} = H(x^n, y^m)$ as the Hamming distance between pairs
 of sequences in the two populations.

We now introduce the following functional

$$F(\mathbf{w}) = \sum_{n,m} d_{nm} w_{nm},$$

with $\mathbf{w} = \{w_{nm}\}$ being a matrix of positive weights. The
 EMD between the two populations \mathcal{X} and \mathcal{Y} is now defined

as the minimum value of function F under the conditions⁸²⁵

$$\sum_{n=1}^N w_{nm} = q^m, \quad \sum_{m=1}^M w_{nm} = p^n, \text{ and } w_{nm} \geq 0$$

775 Intuitively, the weight w_{nm} tells us how much of sequence⁸³¹
 776 x^n is “moved” to sequence y^m . The functional F sums⁸³²
 777 all of these moves and attributes them a cost equal to⁸³³
 778 the Hamming distance d_{nm} . The conditions on weights⁸³⁴
 779 in \mathbf{w} ensure that all the weight p^n of x^n is “moved” to⁸³⁵
 780 elements in \mathcal{Y} and vice versa.⁸³⁶
 781 The minimization is easily performed by standard linear⁸³⁷
 782 optimization libraries. Here, we use the Julia library⁸³⁸
 783 JuMP (Dunning et al., 2017).⁸³⁹

986 **SUPPLEMENTARY MATERIAL**987 **1. Consensus sequence as a predictor for neutrally evolving populations**

988 We consider the case of a neutrally evolving and structure-less population, such as the one in the Wright-Fisher
 989 model of evolution (Sigwart, 2005). At an initial time $t = 0$, the population consists of N individuals with genomes
 990 $(\sigma^1 \dots \sigma^N)$ of length L (not necessarily distinct).

991 We make two hypotheses about this population. We first suppose that *no* mutations occur during the evolution of this
 992 population. This may seem surprising and is of course not true in the case of influenza. This assumption is however in
 993 line with the fact that the object of this work is to predict the outcome of *already existing* mutations in the influenza
 994 population. The prediction of mutations that we have not yet seen is not in its scope. Thus, assuming that no new
 995 mutations take place can be seen as a simple way to model the fact that we have no information about such events.
 996 The second assumption is that the population evolves in a completely neutral way, meaning that the average number
 997 of descendants of each genome σ^n is the same. Let us now consider the population after it has evolved for a long time
 998 $t \gg T$ where T is the typical coalescence time (for the Wright-Fisher model, $T = 2N$). At this point, all individuals in
 999 the future population will descend from a unique individual n_0 in the $t = 0$ population. Our two hypotheses now allow
 1000 us to make two statements. First, since no new mutations are allowed, the population at $t \gg T$ will be clonal, with all
 1001 individuals having genome σ^{n_0} . Second, since the evolution is neutral and does not favour any genome in particular,
 1002 the probability that σ^{n_0} is equal to a given genome σ is $1/N$. In other words, the probability that a genome at $t = 0$
 1003 ultimately becomes the ancestor of all the future population is equal to its frequency in the $t = 0$ population.

1004

1005 We now try to find the genome σ that best predicts the future population on the long run, that is for $t \gg T$. Here,
 1006 we take best to mean that the predictor minimizes $H(\sigma, \sigma^{n_0})$ where H is the Hamming distance defined by

$$H(\sigma^a, \sigma^b) = \sum_{i=1}^L (1 - \delta_{\sigma_i^a, \sigma_i^b}), \quad (1)$$

1007 with σ_i being the character appearing at position i of genome σ and δ the Kronecker delta. Since we do not know n_0 ,
 1008 we have to average over all its possible values. σ must thus minimize the following quantity:

$$\begin{aligned} \langle H(\sigma, \sigma^{n_0}) \rangle_{n_0} &= \sum_{n=1}^N H(\sigma, \sigma^n) \\ &= \sum_{i=1}^L \sum_{n=1}^N (1 - \delta_{\sigma_i, \sigma_i^n}) \end{aligned} \quad (2)$$

by using the definition of the Hamming distance. We now assume that characters at each positions of the genomes can
 be indexed by an integer a running from 1 to q . For instance, if these were amino acid sequences, we could index the
 20 amino acids by a running from 1 to $q = 20$. We rewrite the Kronecker delta in the previous expression using this
 indexation:

$$\delta_{\sigma_i, \sigma_i^n} = \sum_{a=1}^q \delta_{\sigma_i, a} \delta_{\sigma_i^n, a}.$$

1009 We also introduce the *profile* frequencies $p_i(a)$ of the population at time $t = 0$:

$$p_i(a) = \sum_{n=1}^N \delta_{\sigma_i^n, a}. \quad (3)$$

1010 $p_i(a)$ represents the frequency at which character a appears at position i in genomes of the initial population.

1011 Equation 2 now becomes

$$\begin{aligned}
 \langle H(\sigma, \sigma^{n_0}) \rangle_{n_0} &= \sum_{i=1}^L \sum_{n=1}^N \left(1 - \sum_{a=1}^q \delta_{\sigma_i, a} \delta_{\sigma_i^n, a} \right) \\
 &= \sum_{i=1}^N \left(1 - \sum_{a=1}^q \delta_{\sigma_i, a} p_i(a) \right) \\
 &= \sum_{i=1}^L (1 - p_i(\sigma_i))
 \end{aligned} \tag{4}$$

1012 This means that the genome $\sigma = (\sigma_1 \dots \sigma_L)$ which best predicts the future population according to our definition is
 1013 the one that minimizes the quantity $(1 - p_i(\sigma_i))$ for all positions i . This obviously implies that each σ_i must be chosen
 1014 as to maximize $p_i(a)$, that is σ_i must be the character that appears the most frequently at position i . Thus, σ must be
 1015 the *consensus* sequence of the initial population.

1016 2. Predictor based on the local LBI maxima

In figure 17, we use several sequences as a predictor of the future population. Distance between two sets of sequences, *i.e.* the predictor sequences and the ones of the future population, is defined as the Earth Mover's Distance (EMD). Here, we show that for a population evolving under the same hypotheses as in section .1, the best *multiple* sequence long term predictor is again the consensus sequence with weight 1.

Let the predictor be a set of weighted sequences $\{(s^\alpha, q_\alpha)\}$. We again use the fact that in the long term, a unique sequence σ^{n_0} from the present will be the ancestor of the entire population. We want to compute the EMD from the predictor to σ^{n_0} , that is the EMD between the sets $\mathcal{X} = \{(s^\alpha, q_\alpha)\}$ and $\mathcal{Y} = \{\sigma^{n_0}, 1\}$. Applying the definition of the Methods section, it follows that the weights \mathbf{w} are in this case equal to the q_α s. By averaging over all values of n_0 , we now obtain

$$\langle \text{EMD}(\{(s^\alpha, q_\alpha)\}) \rangle_{n_0} = \sum_{n=1}^N \sum_{\alpha} H(s^\alpha, \sigma^n) \cdot q_\alpha.$$

By the same calculation procedure as in the previous section, this expression simplifies to

$$\langle \text{EMD}(\{(s^\alpha, q_\alpha)\}) \rangle_{n_0} = \sum_{i=1}^L \left(1 - \sum_{a=1}^q p_i(a) q_i(a) \right),$$

where the profile of the present population $p_i(a)$ has already been defined, and $q_i(a)$ stands for the profile of the predictor, that is

$$q_i(a) = \sum_{\alpha} \delta_{s_i^\alpha, a} q_\alpha.$$

1017 To minimize this distance, we find a profile $q_i(a)$ that maximizes the quantity $\sum_{\alpha} \delta_{s_i^\alpha, a} q_\alpha$ for each position i . It is
 1018 clear that this is done by assigning a value $q_i(a) = 1$ if a maximizes $p_i(a)$, and $q_i(a) = 0$ otherwise. Thus, the profile of
 1019 the predictor must be that of the consensus sequence, which is only possible if the predictor becomes $\{\sigma^{cons}, 1\}$.

1020 3. Correcting for nested mutations

1021 The analysis of the main text computes probabilities of fixation assuming that all trajectories are independent.
 1022 However, it is well-known that mutations in influenza viruses are nested: they appear on backgrounds that already
 1023 carry other mutations. Since mutations appearing on the same genomes will jointly fix or disappear, many frequency
 1024 trajectories are not independent but correlated. In order to compensate for potential biases due to this effect, we
 1025 attempted to cluster trajectories based on similarity in their strain composition. Our aim is that two trajectories
 1026 corresponding to mutations appearing mostly on the same genomes will be grouped in the same cluster. We then
 1027 conduct the same analysis as in the main text on a set of *effectively independent* trajectories constructed by taking one
 1028 trajectory from each cluster.

In order to perform clustering, we define a distance between trajectories. A frequency trajectory X is characterized by a series of frequency values and a time interval T . $f(t)$ for $t \in T$ corresponds to the frequency at which a given mutation x appears in the population at date t , and we define $S(t)$ as the strains that carry mutation x at date t . With this notation, $f(t)$ is the ratio of the number of elements in $S(t)$ to the total number of strains at date t . Let us now consider two frequency trajectories X_1 and X_2 .

We define the distance $d(X_1, X_2)$ between these two trajectories based on the average similarity of the strains S_1 and S_2 that compose them:

$$d(X_1, X_2) = \frac{1}{|T_1 \cap T_2|} \sum_{t \in T_1 \cap T_2} \frac{|S_1(t) \cap S_2(t)|}{|S_1(t) \cup S_2(t)|},$$

where $T_1 \cap T_2$ is the time interval where both trajectories are active, and $|\cdot|$ denotes the number of elements of a set. The quantity summed corresponds to the Jaccard index between strains composing X_1 and X_2 at a given date. It is 1 if the two trajectories share exactly the same strains for this date, and 0 if they share no strain at all. This leads to the two following properties of d :

- if $d(X_1, X_2) = 0$, then X_1 and X_2 represent the same frequency trajectory. The mutations x_1 and x_2 that they correspond to always appear on the same strains and are totally linked.
- if $d(X_1, X_2) = 1$, then X_1 and X_2 can be considered completely independent. This can be the case if the two trajectories do not occur at the same dates, *i.e.* $|T_1 \cap T_2| = 0$, or if their respective mutations are never present on the same genomes.

we attempt to reduce the potential statistical bias due to the nesting of trajectories by grouping them based on the above defined distance. Given a set of trajectories $\{X\}$, we perform a decomposition of $\{X\}$ into disjoint clusters $C_1(d^*) \cup \dots \cup C_n(d^*) = \{X\}$ where d^* is an arbitrary threshold distance. Clusters are built in such a way that given two trajectories X_i and X_j

$$d(X_i, X_j) \leq d^* \Rightarrow \exists k : X_i, X_j \in C_k$$

and

$$X_i \in C_k \Rightarrow \exists j \in C_k : d(X_i, X_j) \leq d^*.$$

These condition imply that the clusters formed are the minimal ones that guarantee that any two trajectories closer than the threshold distance d^* belong to the same cluster. The number of clusters n depends on the chosen value for d^* .

We compute clusters for different values of d^* for the case of the HA gene in A/H3N2. The top panel of figure S1 shows the number cluster n as a function of d^* . In the $d^* = 0$ case, only trajectories that are exactly identical in terms of strain composition are clustered together. In this case, our clustering amounts to counting mutations that appear on exactly the same strains as one, reducing the number of effective trajectories from 800 to slightly less than 700. For higher values of d^* , the number of clusters steadily goes down until it reaches 1 for $d^* = 1$, which is the maximum value of the distance $d(X_1, X_2)$. The sharp drop in n for $d^* = 0.5$ is explained by the high number of very short (typically one time point) and low frequency trajectories that share one out of two strains.

Since the choice of d^* is arbitrary and since no particular value can be chosen based on the number of clusters $n(d^*)$, we decide to test our clustering strategy for five values, namely $d^* \in \{0, 0.05, 0.1, 0.2, 0.49\}$. The bottom panel of figure S1 shows examples of a cluster for the four non-zero values of d^* . The cluster displayed in each case is the one containing the mutation HA1:33R. As d^* increases, more and more unlike trajectories are grouped together. In the case $d^* = 0.49$, the cluster consists of 13 trajectories, 5 of which end up dying while the rest fix. Since such a high value of d^* results in grouping trajectories that do not have the same fate (fixation or death), we decide to exclude it from the rest of the analysis, resulting in four remaining values $d^* \in \{0, 0.05, 0.1, 0.2\}$.

Once clustering is performed, we re-conduct the analysis of the main text on a set of effective trajectories. This set is constructed by taking one trajectory at random from each cluster. Effective trajectories are then considered independent from each other. The left panel of figure S2 shows the fixation probability of trajectories as a function of their frequency for different values of d^* , for the HA gene of A/H3N2. The result obtained in panel A of figure 2 of the main text is also showed as a reference. For the three lower values of d^* , results do not differ from the one obtained in the main text, even though the number of trajectories in each frequency bin has dropped as can be seen in the right

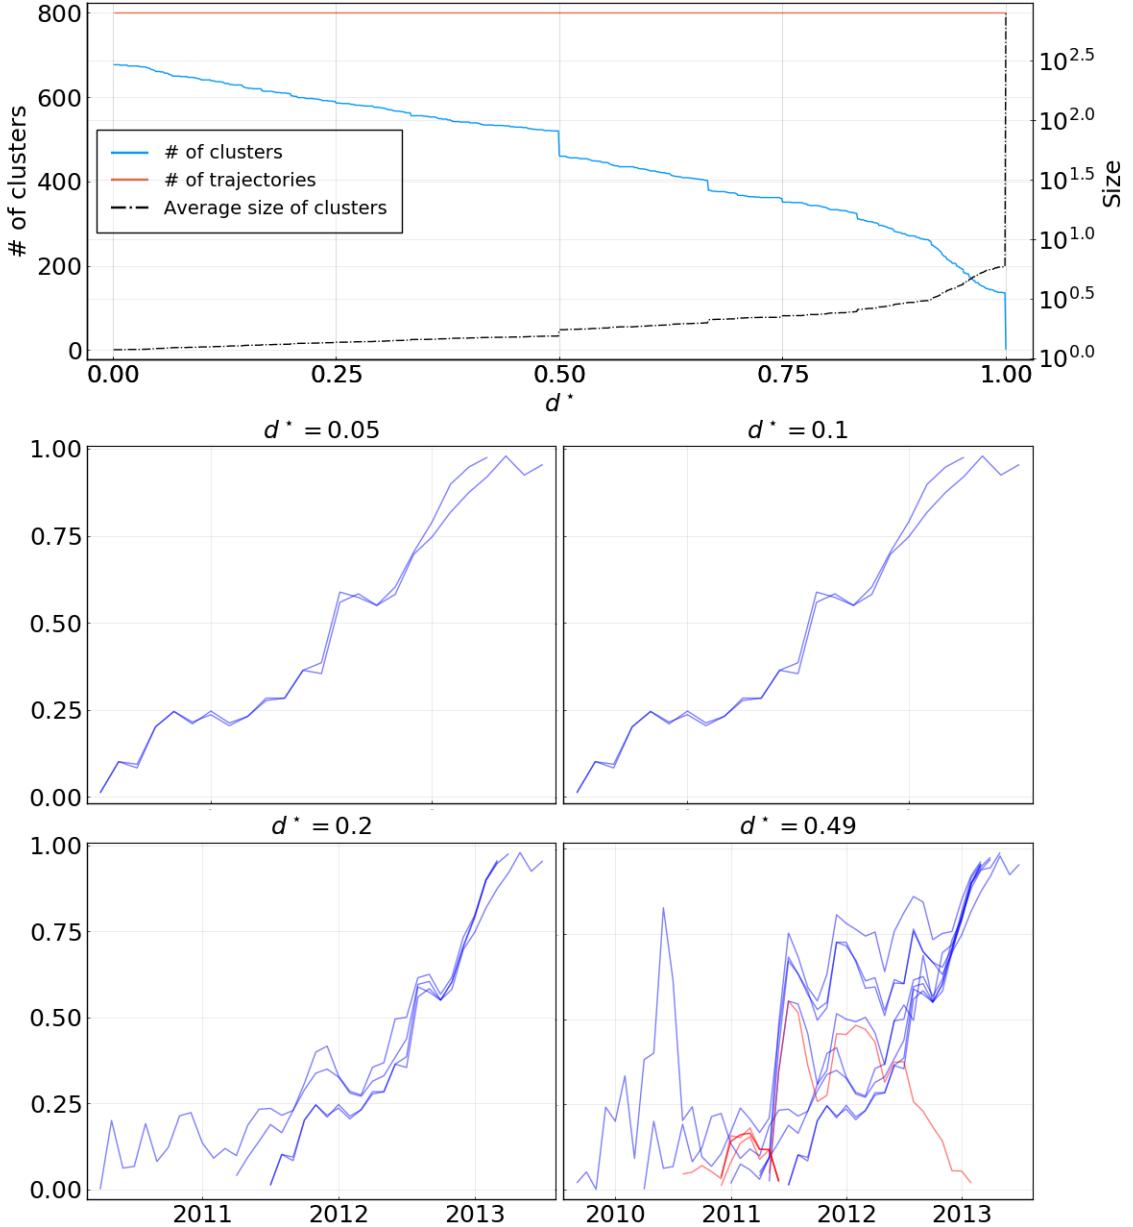

Figure S 1 **Top:** Left-axis: number n of clusters as a function of the threshold distance d^* . The total number of trajectories is shown as a flat orange line. Right-axis: average size of clusters as a function of d^* . **Bottom:** Examples of clusters for four values of d^* . The four clusters displayed are the ones to which mutation HA1:33R belongs to.

panel of figure S2. This indicates that grouping together trajectories that share most of their strains, and are thus very correlated, does not modify the computed fixation probability in any way. For the higher value $d^* = 0.2$, fixation probability drops slightly across all frequency bins, suggesting that fixating trajectories tend to be grouped together more frequently. However, this drop remains of limited amplitude.

Overall, this analysis leads us to think that even though mutations in influenza may be nested, considering trajectories as independent does not result in strong statistical biases. Indeed, clustering similar trajectories together does significantly modify results presented in the main text.

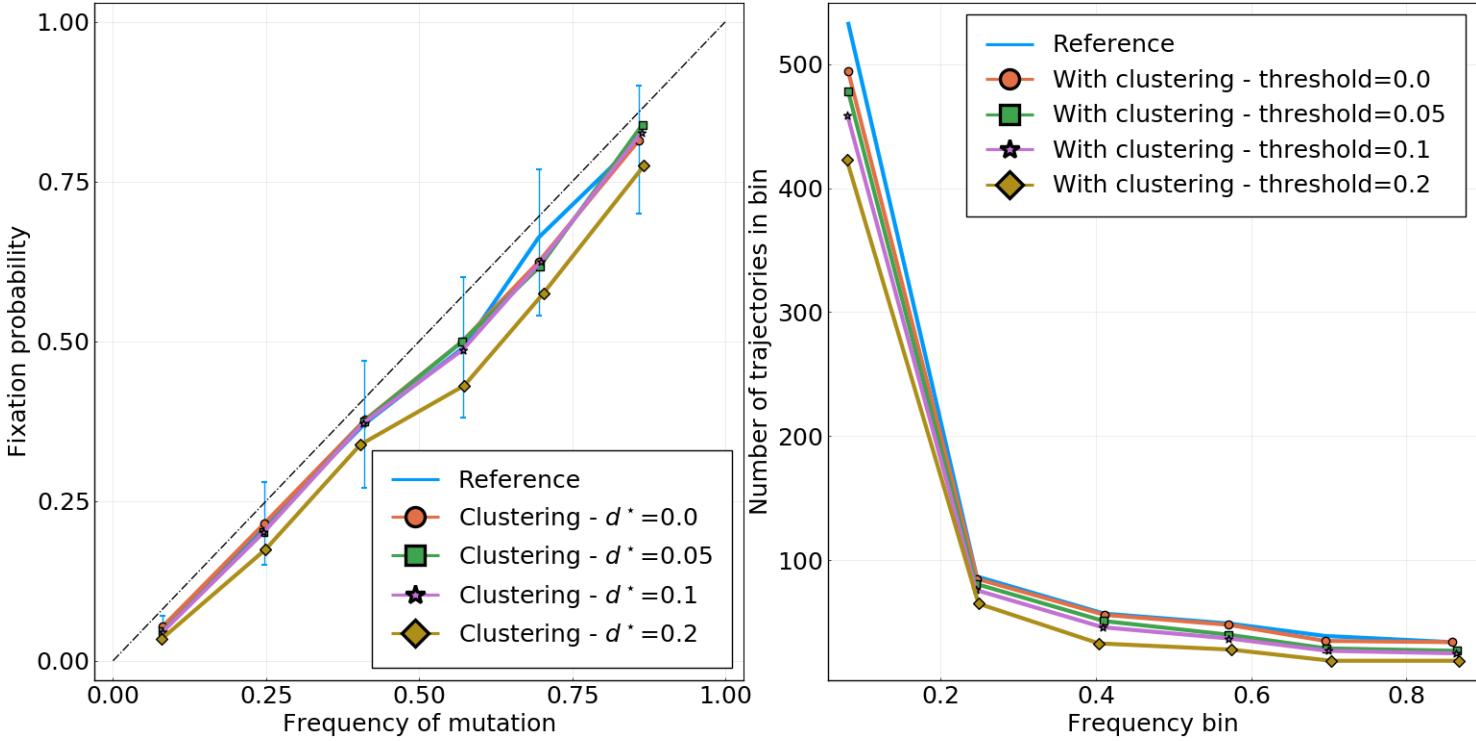

Figure S 2 **Left:** Fixation probability of trajectories as a function of probability for four values of d^* . The reference curve is the same as in panel A of figure 2 for the HA gene. For readability, error bars are only displayed for the reference curve. **Bottom:** Number of trajectories in each frequency bin corresponding to the left panel.

1069 4. Biases in frequency estimations

1070 The frequency of mutations in a given time-bin is simply performed by computing their frequency in sequences
1071 sampled in that time bin. This leads to potential biases in estimating frequencies, that arise for two reasons:

- 1072 (i) A mutation present at frequency p in the population might be observed at another frequency $f \neq p$ if f is
1073 estimated using a sub-sample of the population.
1074 (ii) For a neutrally evolving population, the distribution of frequencies of alleles is of the form $P(p) \propto 1/p$. This
1075 means that the amount of alleles at frequency p is lower when p is higher.

1076 To illustrate (i), let us compute the probability that a mutation present at “real” frequency p in the population is
1077 found to be in a given frequency bin $[f_1, f_2]$ when p is estimated from a sample of size n . The sample consists of n
1078 observations $\{x_i\}$ with $1 \leq i \leq n$, with $x_i = 1$ if sequence sequence i of the sample bears the mutation, and $x_i = 0$ if
1079 not. If n is small with regard to the total population size, we can consider the x_i as random variables with a binomial
1080 distribution, meaning that $P(x_i = 1) = p$ and $P(x_i = 0) = 1 - p$. The empirical frequency f is then estimated by
1081 taking the average of the x_i variables, that is $f = (x_1 + \dots + x_n)/n$. If those are independently sampled and n is large
1082 enough, the probability of measuring value f is given by the Central Limit Theorem:

$$P_{n,p}(f) \propto e^{(f-p)^2/2\sigma^2}, \text{ where } \sigma^2 = \frac{p(1-p)}{n}. \quad (5)$$

1083 To compute the probability that this mutation is found in a given frequency bin $[f_1, f_2]$, we integrate this distribution:

$$P_{f_1, f_2}(p, n) = \int_{f_1}^{f_2} dx P_{n,p}(x). \quad (6)$$

1085 Function $P_{f_1, f_2}(p, n)$ is shown as a function of p for a fixed interval and for different values of n in the first panel of
1086 figure S3. Note the asymmetry of it: the variance of a binomial distribution of parameter p is small when p is close to

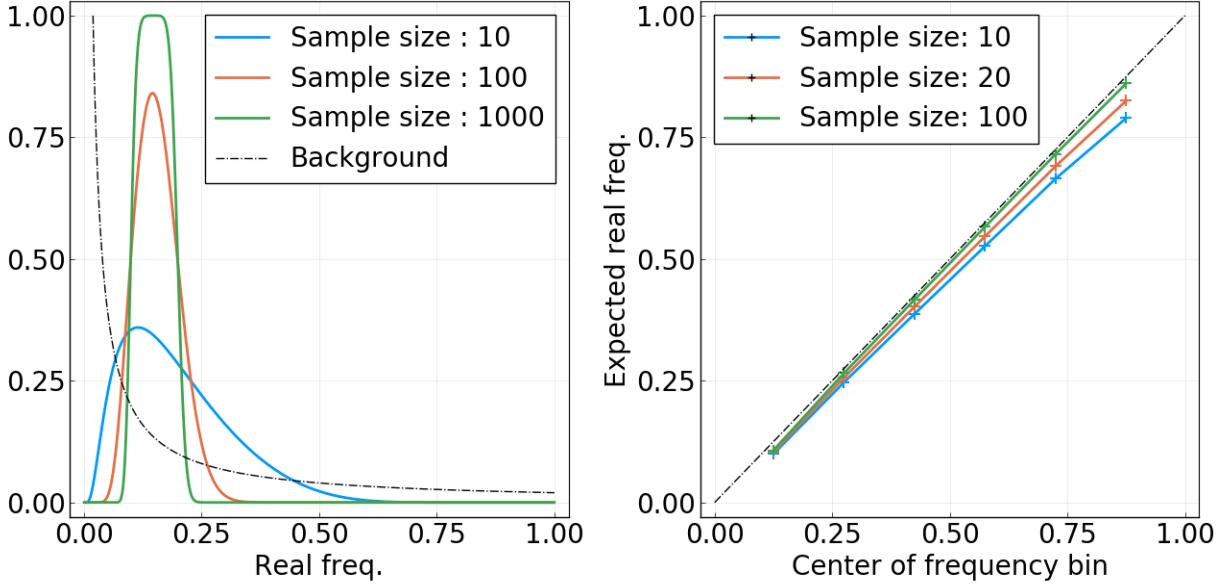

Figure S 3 **Left:** For a mutation present at frequency p in the population, probability of being observed in the frequency bin $[0.1, 0.2]$ as a function of p and for different sample sizes n . The dashed black line sketches the (non-normalized) background distribution $P_b(p)$. **Right:** Expected “real” average frequency of mutations found in frequency bin $[f_1, f_2]$ as a function of the centre of the bin $(f_1 + f_2)/2$, for different sample sizes.

1088 0 or 1, and goes through a maximum at $p = 0.5$. For this reason, mutations present at frequency p close to 0.5 have a
 1089 higher probability of being observed in other frequency bins. On the contrary, this is unlikely for very rare or very
 1090 frequent mutations.

1091 We now try to estimate biases in frequency estimation due this phenomenon. Given a set of mutations that have
 1092 been measured in frequency bin $[f_1, f_2]$, what is the average *real* frequency of these mutations? To compute this, we
 1093 need to sum $P_{f_1, f_2}(p, n)$ over all possible real frequencies p , giving us the amount of mutations that are observed in
 1094 interval $[f_1, f_2]$, and weigh this sum by the frequency value p as well as by the background distribution of frequencies
 1095 $P_b(p) \propto 1/p$. This last quantity represents the expected amount of mutations that are present at frequency p in the
 1096 population. Note that there is no divergence problem as the smallest non zero frequency is $1/N$, where N is the
 1097 population size. This leads us to the following expression for the average of “real” frequencies:

$$\langle p \rangle(f_1, f_2, n) = \int_{1/N}^{1-1/N} dp P_{f_1, f_2}(p, n) P_b(p) p \\ = \int_{1/N}^{1-1/N} dp P_{f_1, f_2}(p, n). \quad (7)$$

1098 We have not made normalization explicit in these equations. It is simply achieved by dividing the above expression by
 1099 $\int dp P_{f_1, f_2}(p, n) P_b(p)$.

1100 In the second panel of figure S3, $\langle p \rangle(f_1, f_2, n)$ is plotted as a function of the centre of the interval $[f_1, f_2]$ and for
 1101 different values of n . For sample sizes $n > 100$, the biases due to this effect are almost non existent. For smaller
 1102 samples, for instance $n = 10$, they are small but non negligible. However, we argue that this is not a significant problem
 1103 with respect to the main results presented in this article. First, figure S8 shows that sample sizes of the order of $n = 10$
 1104 are only the case for a few months in the period going from year 2000 to 2018. From 2010 and onwards, more than a
 1105 hundred sequences are available per month for most months. Secondly, even if most samples were in the $n = 10$ case,
 1106 deviations shown in figure S3 are small enough that results shown in figures 2 and 3 would be *qualitatively* unchanged.
 1107 Note that using the centre of the interval as a reference in figure S3, *i.e.* $(f_1 + f_2)/2$, would be correct in the case of
 1108 a very large n and a flat background distribution $P_b(p)$. For figures 2 and 3 of the main text however, the average
 1109 frequency of mutations found in an interval $[f_1, f_2]$ is computed by taking the average of the observed frequencies, and
 1110 not the centre of the interval. This partially takes into account biases considered here, as the background distribution
 1111 $P_b(p)$ is then accounted for, even though it is equivalent to assuming infinite sample sizes.

1112 5. Cutting off the HA1 159S branch

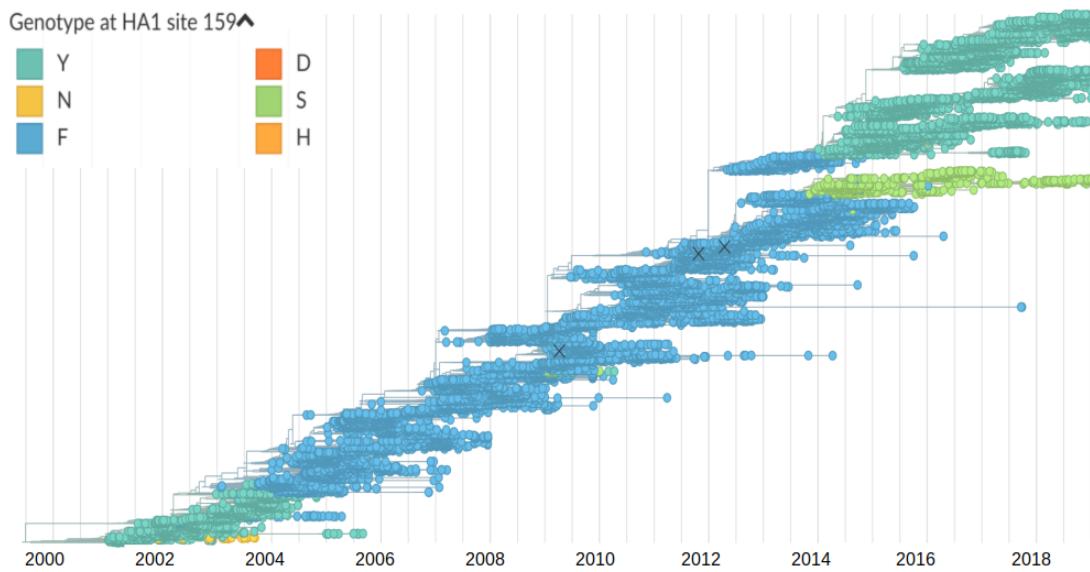

Figure S 4 Tree used for this study, based on a random selection of 100 strains per month from year 2002 to 2018. Nodes and branches are colored according to the amino acid found at position HA1:159. The HA1 159S mutation is visible as a thin but long light-greened color branch, coalescing with the “trunk” around 2013.

1113 The analysis of the main text is in a large part based on the probability of fixation of mutations. The motivation
 1114 underlying this choice is the relatively short coalescence time of the A/H3N2 influenza population, typically around
 1115 three years. This can be seen in figure 2 of the main text, which shows the typical lifetime of frequency trajectories,
 1116 ending in fixation or loss after at most 3 years in most cases. The tree in figure S4 is another illustration of this: for
 1117 the most part of it, a “trunk” is clearly identifiable, and lineages that depart from it have a relatively short lifetime.
 1118 This is no longer the case since the year ~ 2013: two clades have been competing since then, with no definite way to
 1119 identify a trunk in the tree. The clade defined by the HA1 159S mutation, colored in light green on figure S4, is one of
 1120 these two competing lineages. Because of this particular situation, the number of mutations fixating in the population
 1121 is strongly reduced, as a mutation must appear in both clades to reach a frequency of 1. This is a potential flaw in our
 1122 analysis, which concentrates on mutations fixating.

1123 For this reason, we decided to re-run our analysis after having cut off the HA1 159S clade. In other words, we remove
 1124 from the set of sequences those that carry the HA1 159S mutation. Results are shown in figures , equivalent to figures 2
 1125 and 3 of the main text. It is clear that qualitative results are left unchanged when this competing clade is removed.
 1126 This can be surprising, as almost no complete fixation of an amino acid mutation has occurred since 2013. Cutting off
 1127 the HA1 159S branch should thus result in many new fixations, changing the analysis. The reason for the similarity
 1128 of results can be explained: fixation (resp. loss) of a mutation are defined here as the frequency of this mutation
 1129 being measured above 95% (resp. 5%) frequency for two months in a row. As the HA1 159S clade is rather sparsely
 1130 populated, it reaches frequencies lower than 5% two times (in 2015 and 2017), allowing mutations in the competing
 1131 clade to “fix” as defined here. Thus, removing strains carrying HA1 159S does not introduce a significant amount of
 1132 “new” fixation events.

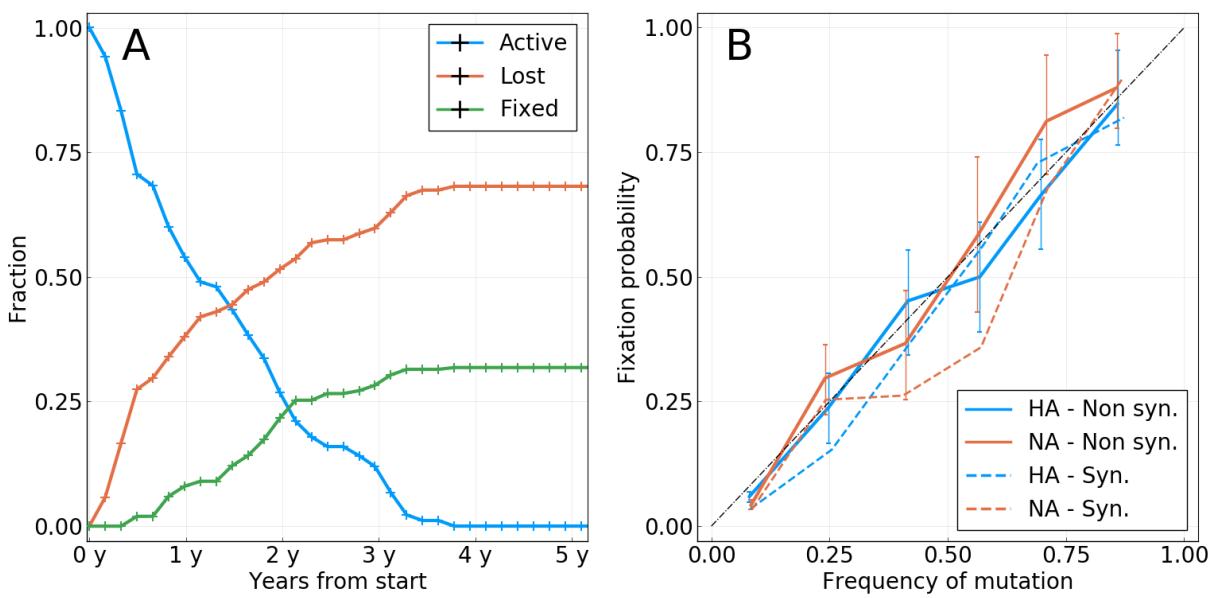

Figure S 5 Equivalent to figure 2 of the main text, but with strains carrying the HA1 159S mutation removed.

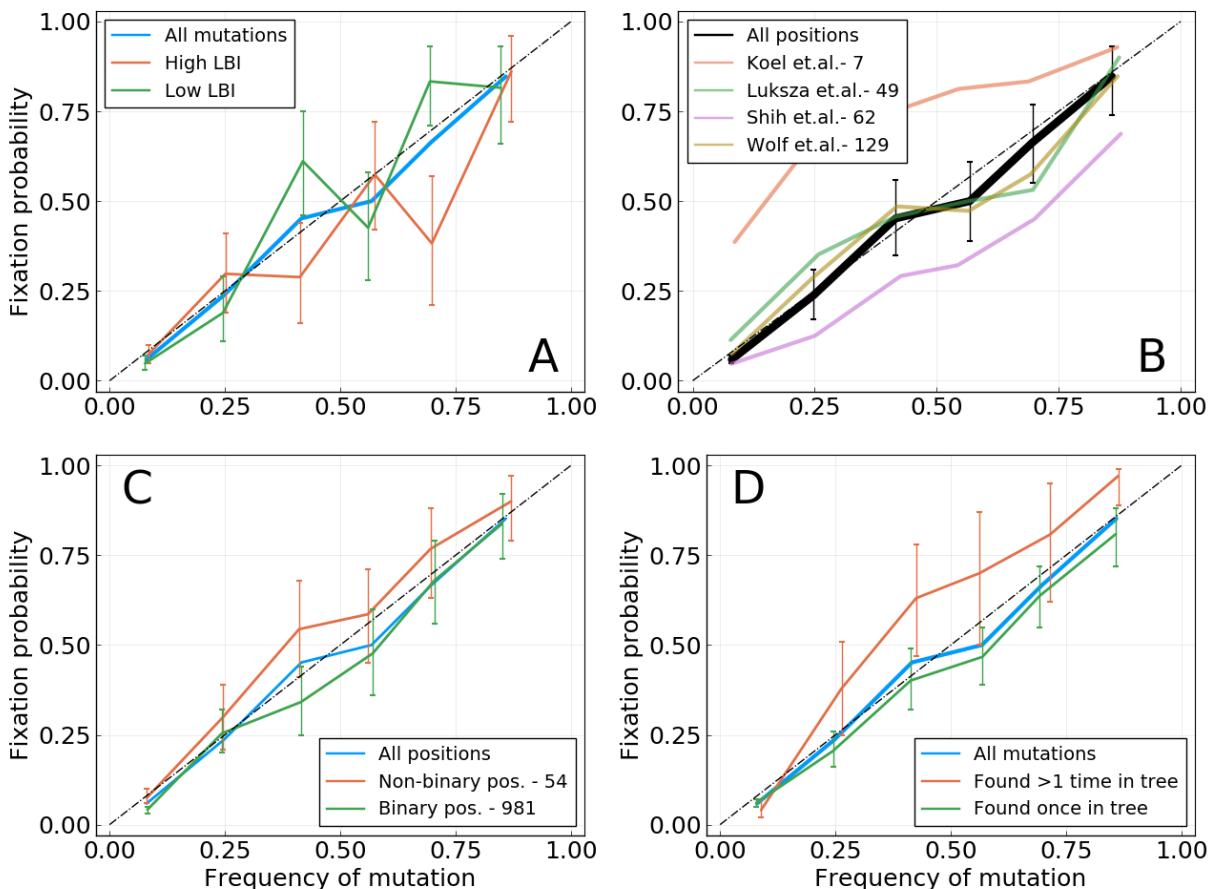

Figure S 6 Equivalent to figure 3 of the main text, but with strains carrying the HA1 159S mutation removed.

1133 **6. Probability of fixation in single locus model of evolution**

1134 In (Kimura, 1964), Kimura investigates a simple model of evolution with a single locus and a population of size
 1135 N . In this framework, a mutation at this locus with fitness effect s and observed at frequency f has the following
 1136 probability of fixation:

$$P_{fix}(f|s, N) = \frac{1 - e^{-sNf}}{1 - e^{-sN}}. \quad (8)$$

1137 Expanding this formula for $sN \ll 1$, that is in the weak selection regime, yields at the first order

$$P_{fix}(f|s, N) = f + f(1 - f) \frac{sN}{2}. \quad (9)$$

1138 Equation 9 tells us two things. First, when the mutation is neutral, that is $s = 0$, we have $P_{fix}(f) = f$. This naturally
 1139 confirms the result obtained for a neutral model of evolution. Seconds, when $sN \neq 0$, we can expect deviations from
 1140 the diagonal in a P_{fix} against f plot. The sign of these deviations is determined by the sign of s , with beneficial
 1141 mutations being found above diagonal while deleterious one are found below. The amplitude of these deviations
 1142 depends on the strength of selection sN , as well as on the frequency through the $f(1 - f)$ term, making them larger
 1143 for $f \sim 0.5$.

Table S I The 30 trajectories that took place between year 2000 and year 2018 and resulted in fixation. Columns **Shih**, **Luksza** and **Koel** respectively indicate whether the position is found in the epitopes lists in (respectively) (Shih et al., 2007), (Luksza and Lässig, 2014) and (Koel et al., 2013). The **Tree counts** column indicates the number of times the mutation corresponding to the trajectory can be found in the phylogenetic tree. Note that a trajectory is only shown in the table if the sequenced population counts more than 10 strains at its time of fixation. This explains that only 30 trajectories are displayed, whereas more mutations did fix in this period of time.

| Gene | Position | AA | Start date | End date | Fixation | Max. freq. |

Table S II Trajectories of mutations at epitope positions in (Shih et al., 2007) (*Shih et. al.*) that have been observed at least once above frequency 0.25. The **Fixation** column indicates whether the mutation has fixed, disappeared, or is still polymorphic as of October 2018. The **Max.freq.** column indicates the maximum frequency reached by the trajectory. A maximum frequency of 1 for mutations that finally disappear is explained by trajectories reaching frequency 1 for one time bin and going back to lower values for following ones (a frequency above 0.95 for two time bins in a row defines fixation).

Table S IV Same as table SII, for (Koel et al., 2013) (*Koel et. al.*).

1145 8. Supplementary figures

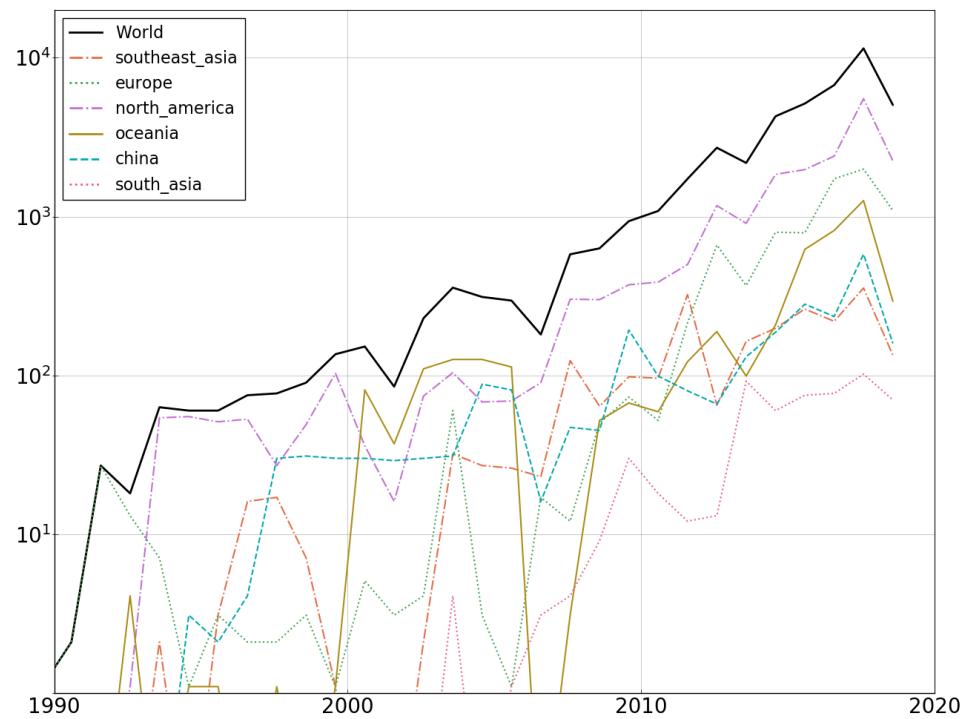

Figure S 7 Number of A/H3N2 HA sequences per year from year 1990.

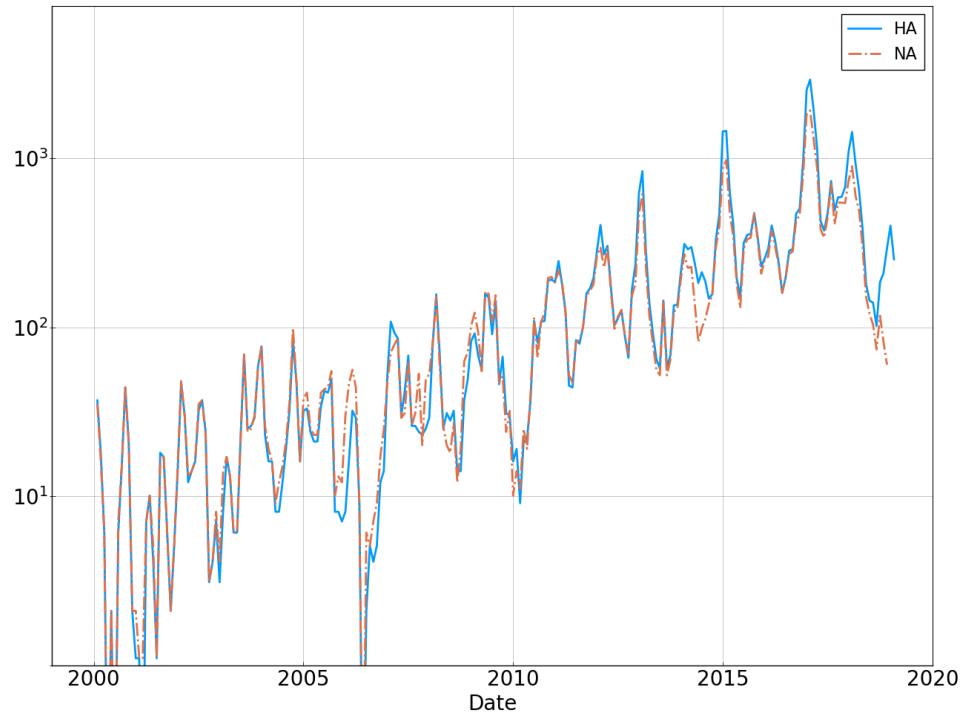

Figure S 8 Number of H3N2 HA and NA sequences per month from year 2000.

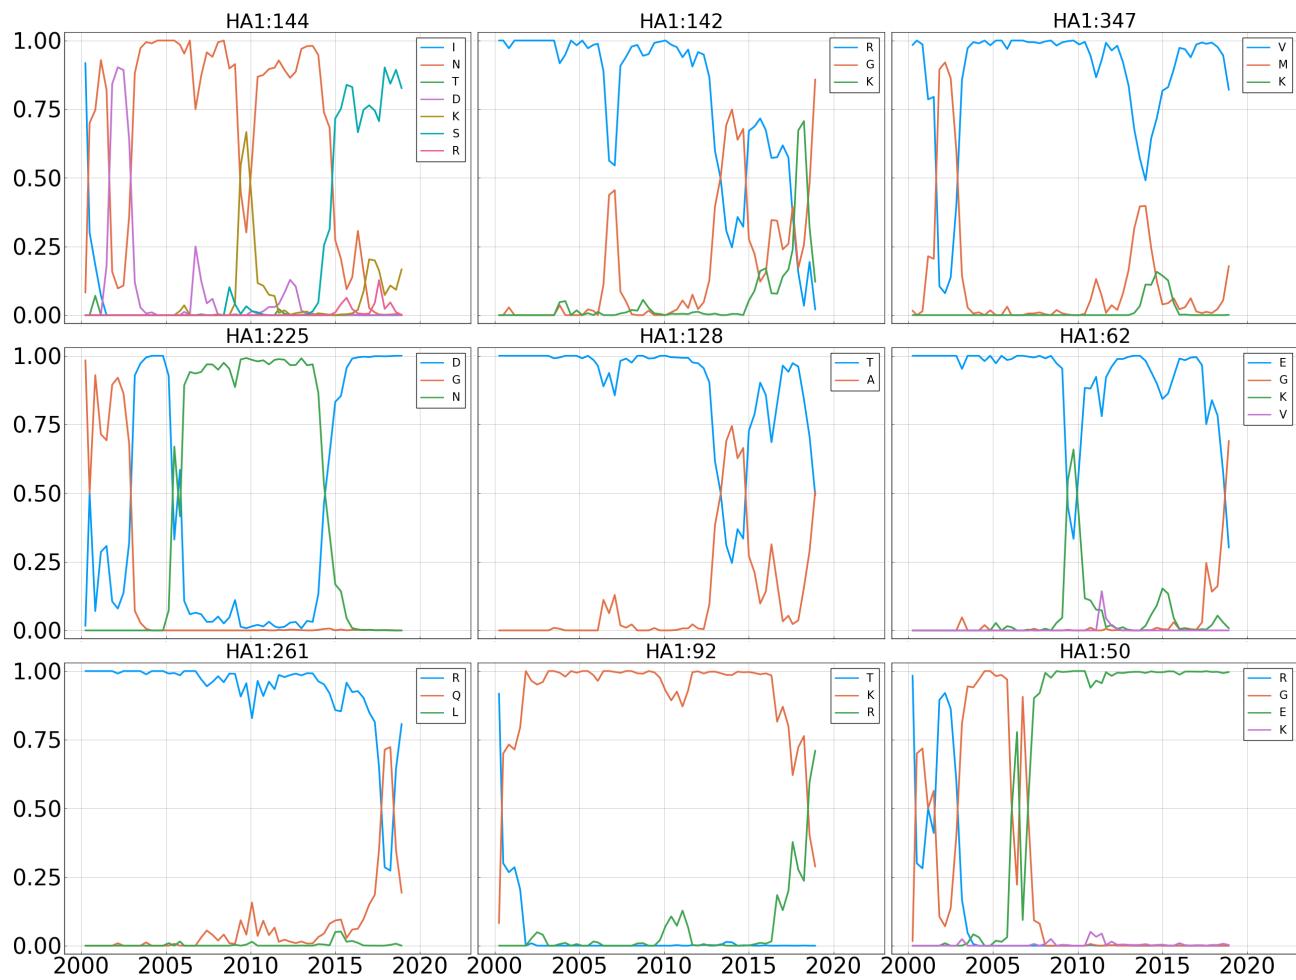

Figure S 9 Frequency trajectories for the 9 most entropic positions in the A/H3N2 HA protein.

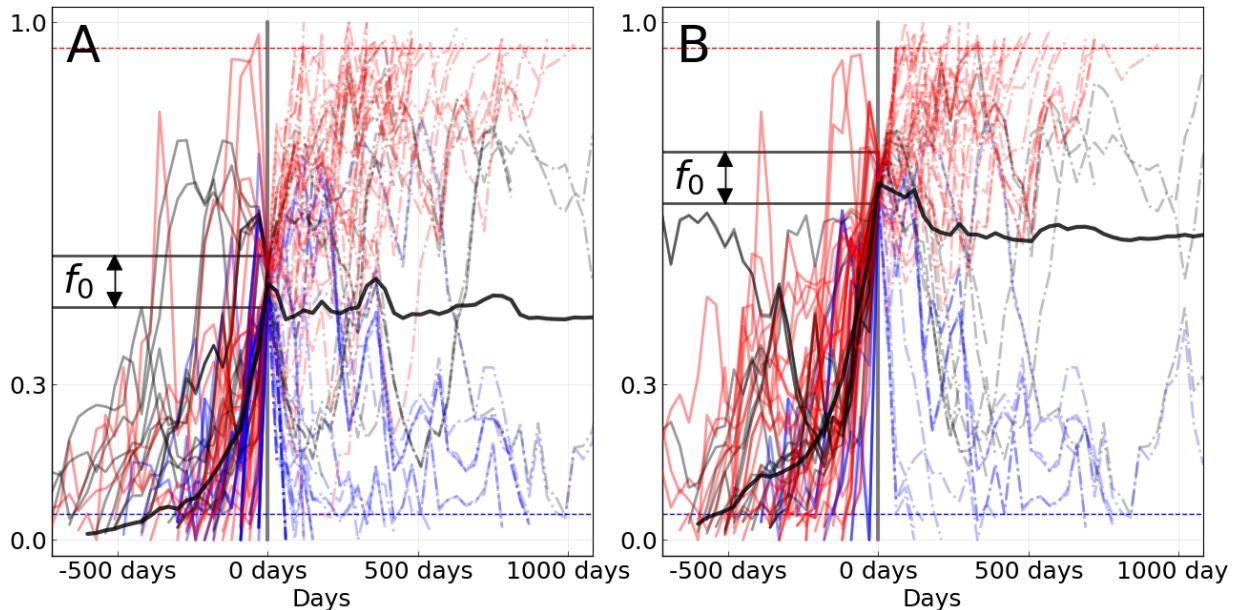

Figure S 10 Equivalent to panel **B** of figure 1 of the main text for A/H3N2, with f_0 equal to 0.5 in **A** (76 trajectories), and 0.7 in **B** (63 trajectories).

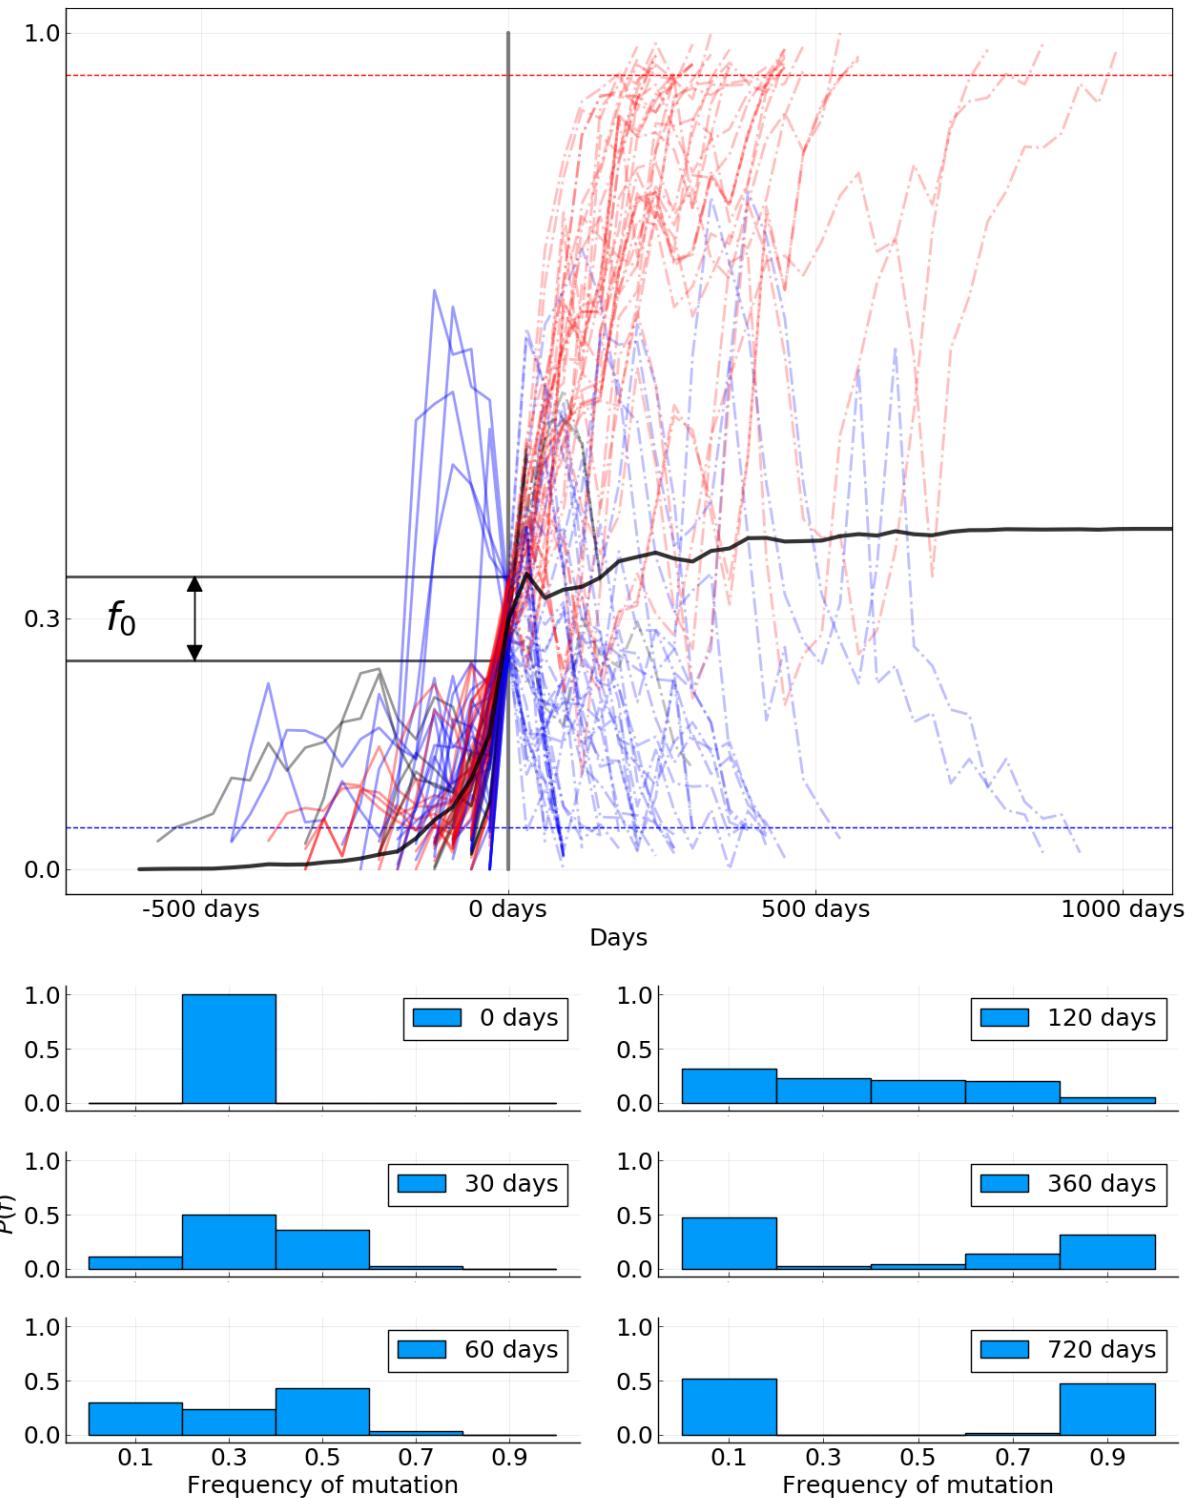

Figure S 11 Equivalent to panels **B** and **C** of figure 1 of the main text for A/H1N1pdm influenza. 89 trajectories are shown and participate to the mean (thick black line).

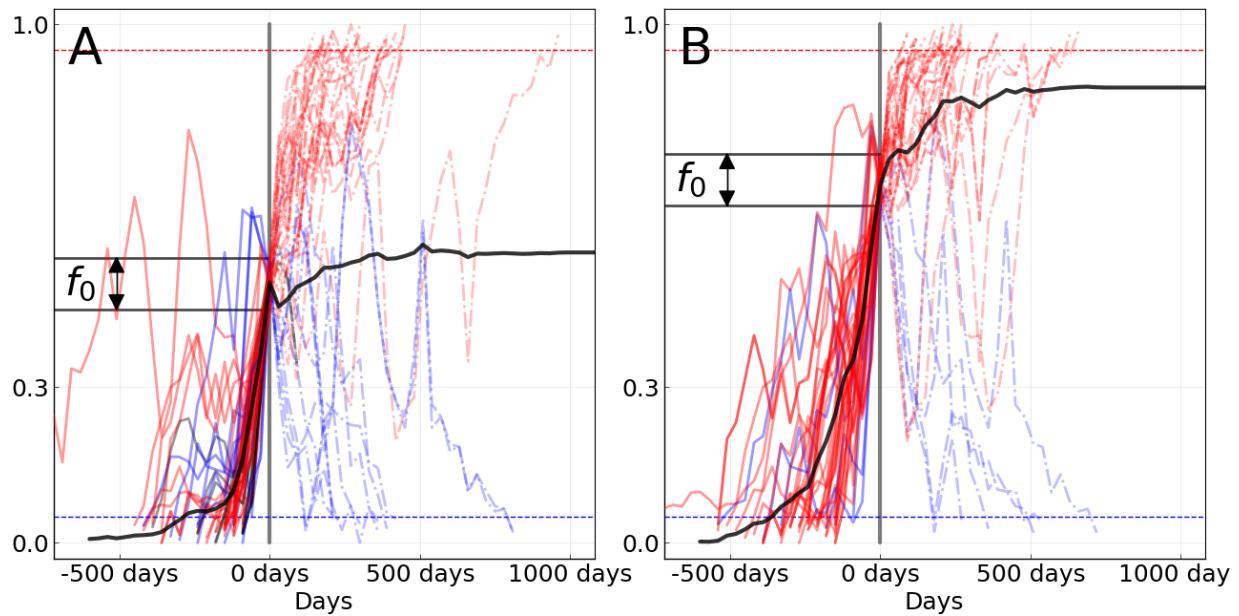

Figure S 12 Equivalent to panel **B** of figure 1 of the main text for A/H1N1pdm, with f_0 equal 0.5 in **A** (50 trajectories), and 0.7 in **B** (41 trajectories).

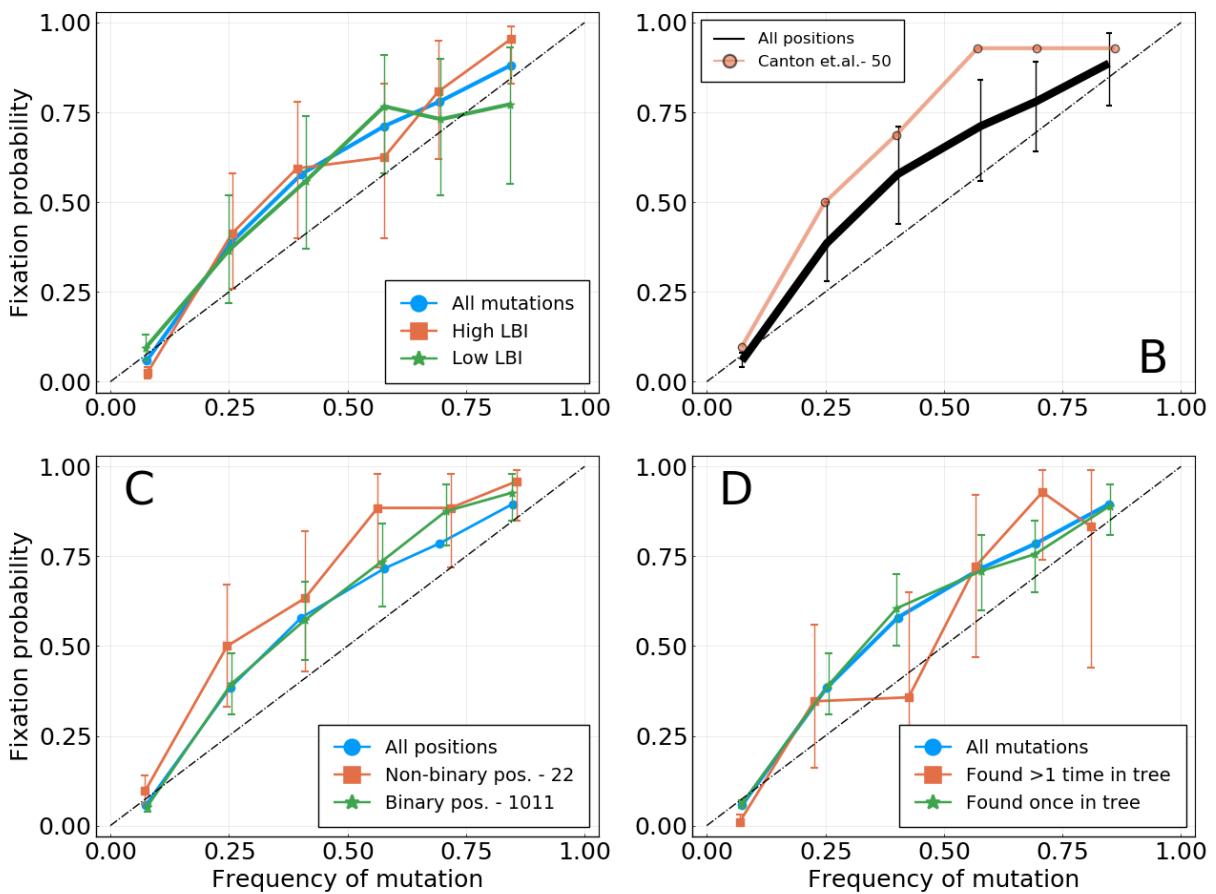

Figure S 13 Equivalent of figure 3 of the main text for the HA gene of A/H1N1pdm influenza. Fixation probability $P_{fix}(f)$ as a function of frequency. **A:** Mutation with higher or lower LBI values, based on their position with respect to the median LBI value. **B:** Different lists of epitope positions in the HA protein. The authors and the number of positions is indicated in the legend. **C:** Mutations for binary positions, *i.e.* positions for which we never see more than two amino acids in the same time bin. **D:** Mutations that appear once or more than once in the tree for a given time bin.

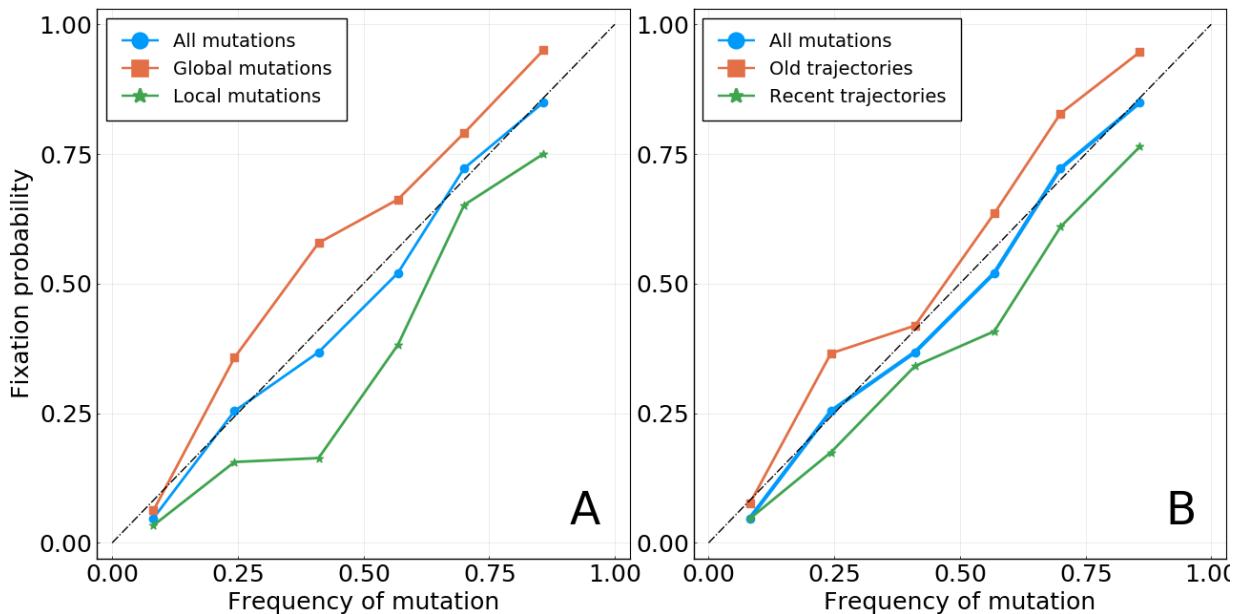

Figure S 14 Based on A/H3N2 HA and NA. **A:** Mutations with a higher or lower geographical spread, based on the median value of the score used (see Methods). Note: the words *local* and *global* only reflect the position of the geographic spread of the mutation relative to the median value computed for all mutations found at this frequency. As this median value may change with the considered frequency bin, so does the definition of local and global mutations. **B:** Mutations whose trajectories are older or more recent, based on the median age of trajectories when reaching the considered frequency f .

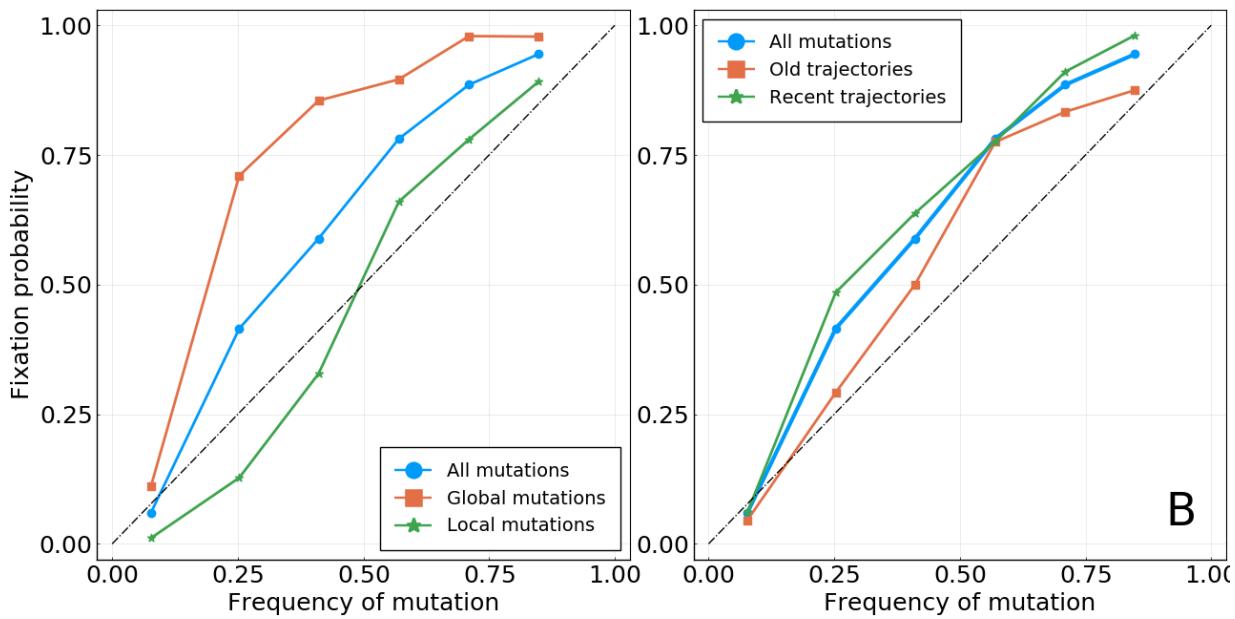

Figure S 15 Based on A/H1N1pdm HA and NA. **A:** Mutations with a higher or lower geographical spread, based on the median value of the score used (see Methods). Note: the words *local* and *global* only reflect the position of the geographic spread of the mutation relative to the median value computed for all mutations found at this frequency. As this median value may change with the considered frequency bin, so does the definition of local and global mutations. **B:** Mutations whose trajectories are older or more recent, based on the median age of trajectories when reaching the considered frequency f .

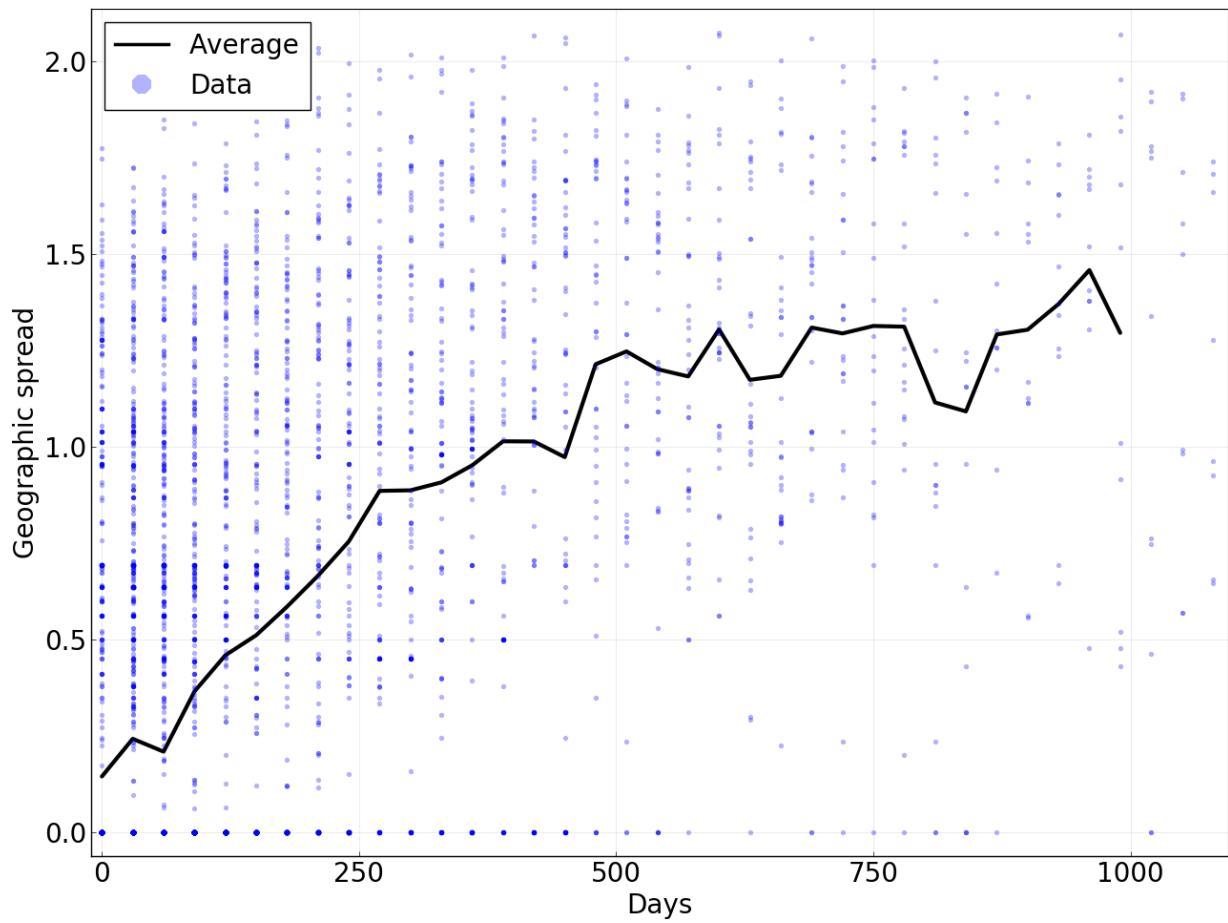

Figure S 16 Geographic spread of mutations as a function of the time for which they have been present in the population above a frequency of 5%. Points represent individual mutations and for a population in a given time bin. The line is the average of dots for a given value on the x -axis. Based on data for A/H3N2 HA.

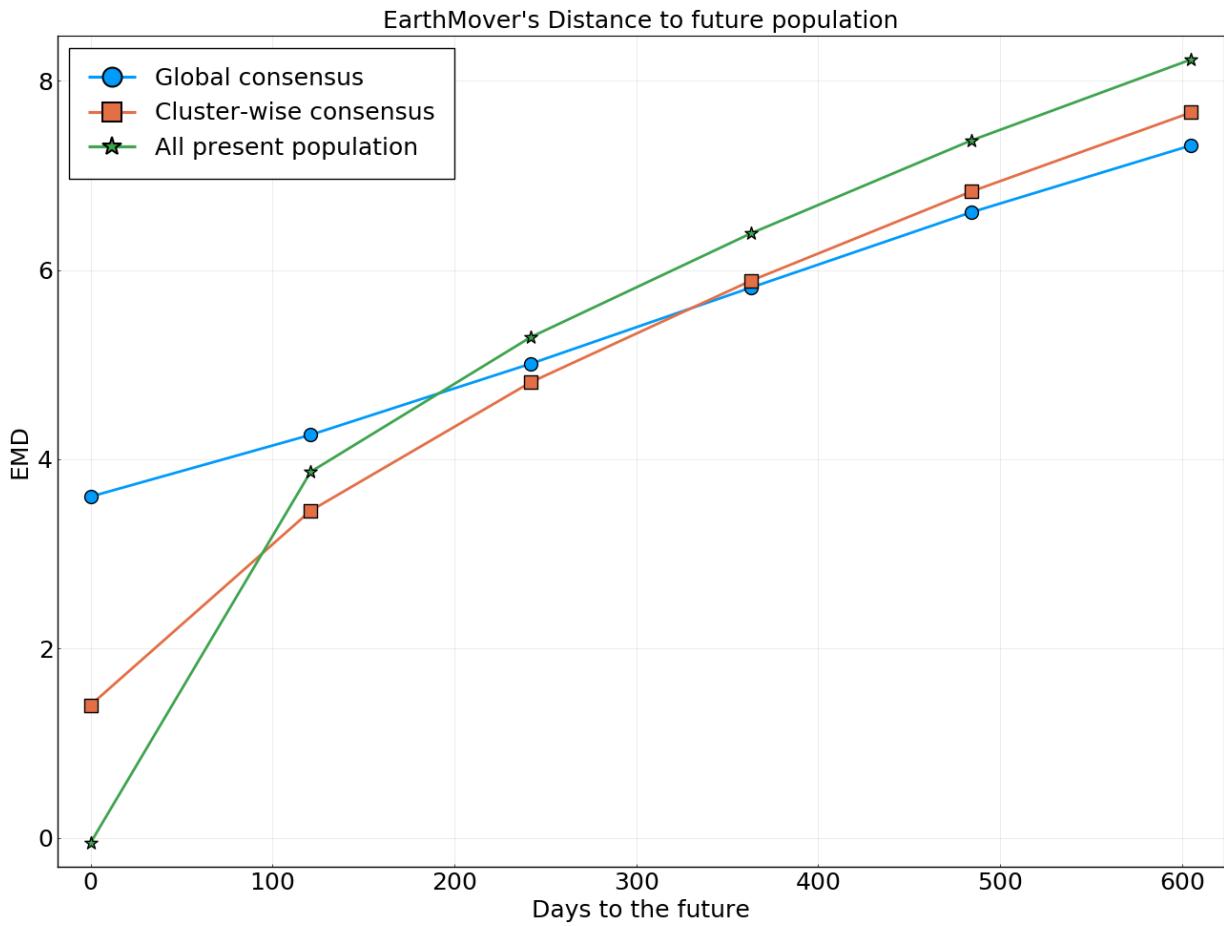

Figure S 17 Earth mover's distance to the future population for different predictors. A present population consists of all A/H3N2 HA sequences sampled in a 4 months time window. Quantities are averaged over all possible "present" populations from the year 2002. Predictors are: **Global consensus**: Consensus sequence of the present population. Best long-term predictor for a structure-less neutrally evolving population. **All present population**: All sequences in the present population. Perfect predictor if the population does not change at all through time. **Cluster-wise consensus**: Consensus sequence for each cluster in the present population. Clusters are based on local maxima of the LBI. Sequences are assigned to a given cluster based on their tree branch-length distance to the corresponding local maximum.

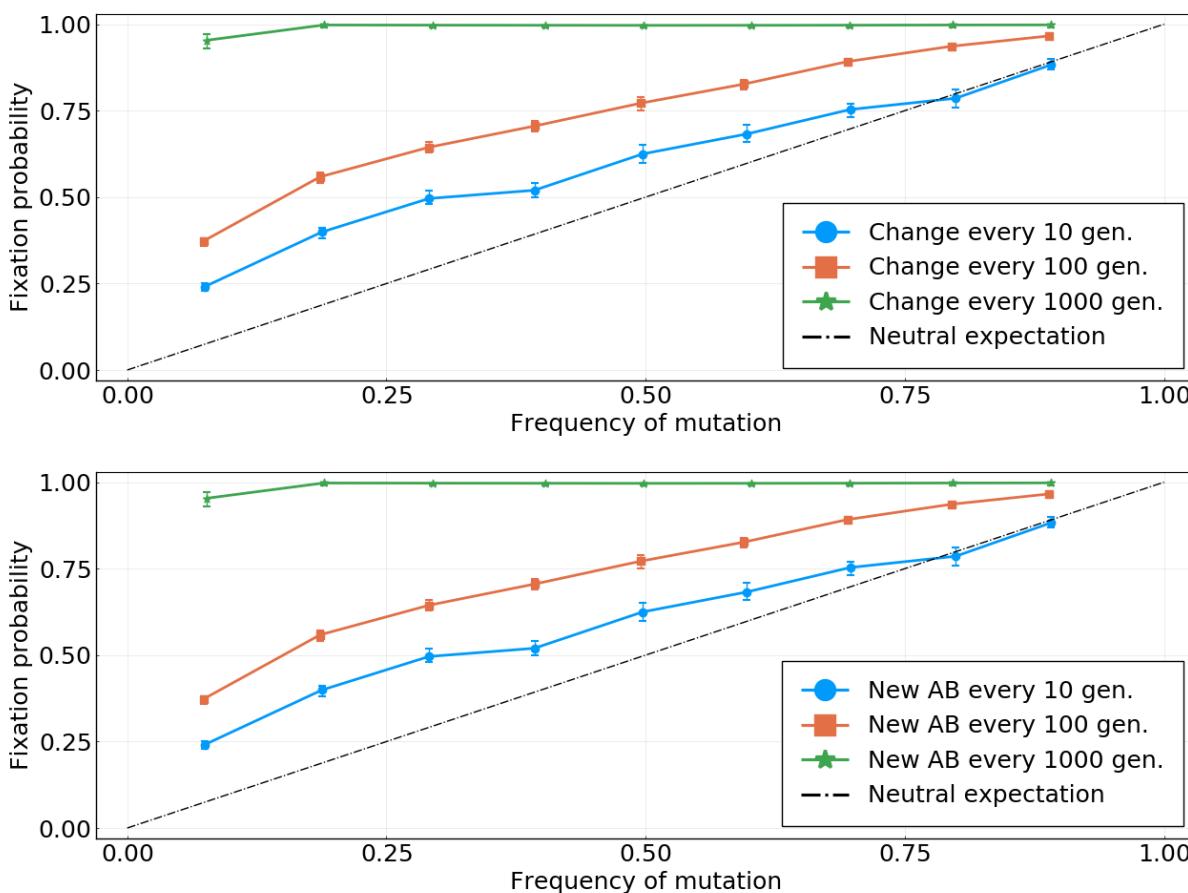

Figure S 18 Fixation probability as a function of frequency for the simulations discussed in the main text. **Top:** Simulation without antibodies. The three colored curves reflect different rate of change for the fitness landscape. Visual inspection of the frequency trajectories indicates a typical sweep time of ~ 400 generations. **Bottom:** Simulation with antibodies. The different colored curves indicate the rate at which antibodies are introduced.

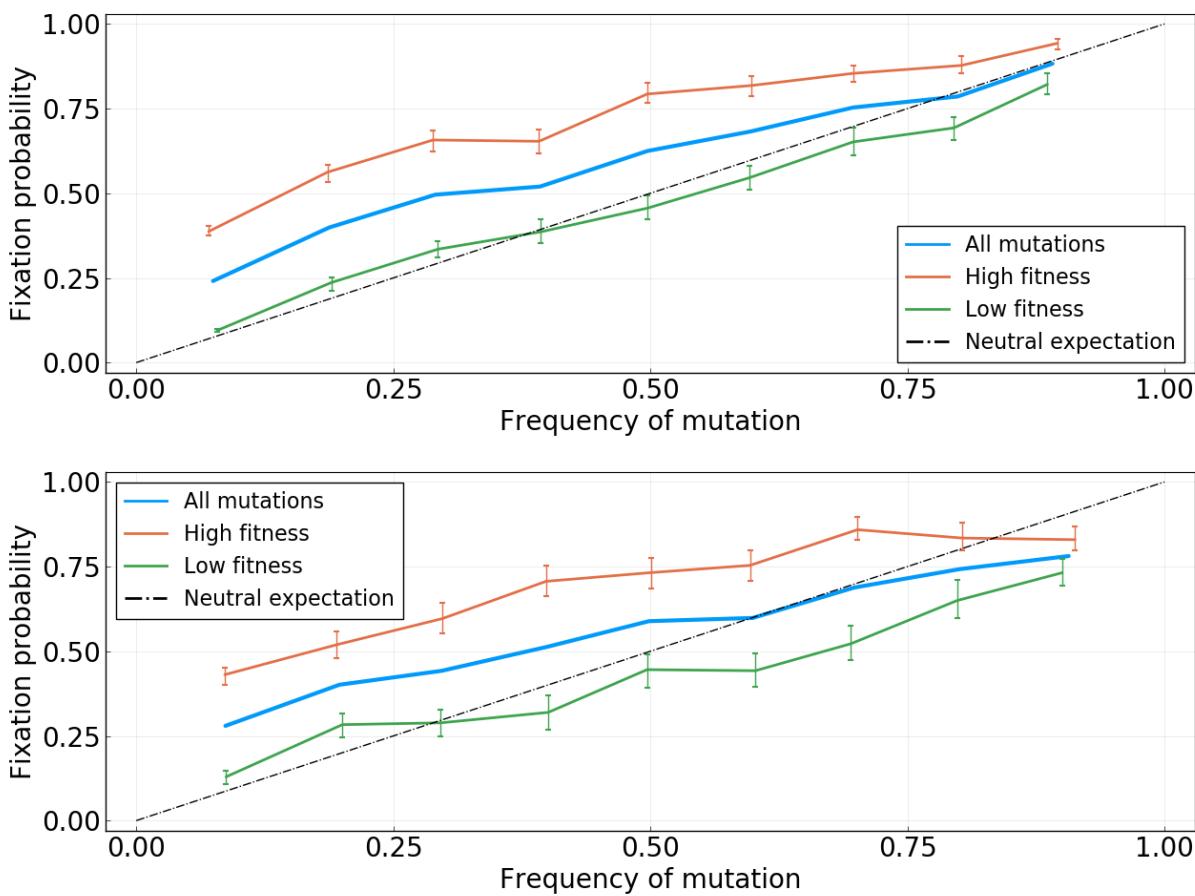

Figure S 19 Fixation probability as a function of frequency for the simulations discussed in the main text, with trajectories stratified according to real fitness values. “High” and “low” fitness classes are defined with respect to the median value. **Top:** Simulation without antibodies and with changes to the fitness landscape every $dt = 10$ generations. **Bottom:** Simulation with antibodies, with a new antibody every $dt = 10$ generations.
